Nutrition and the Humoral Regulation of Growth

21

William E. Russell, MD and J. Marc Rhoads, MD

Hormones and nutrients interact to influence growth at all levels of biologic organization. Growth is often loosely defined to include all aspects of somatic enlargement and maturation. The principal impact of malnutrition on the growing child is to diminish or reverse weight gain. When malnutrition is of sufficient duration or intensity, statural growth is retarded, although under some unusual circumstances, malnutrition may selectively impair linear growth without a preceding or concomitant loss in weight.[1] The manifestations of malnutrition effects on growth are often subtle, frequently masquerading as social, ethnic, or racial characteristics. In a study of ethnically homogeneous conscripts in the Polish army, Bielicki and colleagues[2] found that young men from large families, from the countryside, and from lower socioeconomic classes were smaller than their counterparts from smaller, urban, and more privileged families. These authors concluded that the negative impact of these variables on stature could all be attributed to suboptimal nutrition. On a large scale, the effect of malnutrition is often so striking as to produce major population differences in stature that appear to be genetic. For instance, prior to World War II, native Japanese were smaller than Americans of European ancestry and smaller than Japanese-Americans raised in the United States.[3] However, with the significant nutritional improvements that took place in Japan following World War II, these differences vanished.[4]

NUTRIENTS, HORMONES, AND GROWTH

Hormones and Growth Factors

Hormones are generally defined as the secretions of glands that specialize in their production; classic hormones, acting through an endocrine mode of regulation, therefore require conveyance through the circulation to alter the function of distant tissues. Their concentrations and association with binding proteins can be readily measured in the blood and other body fluids. Regulation occurs not only through changes in the concentration of the hormone, but also in the number and cellular distribution of their peripheral receptors and in the systems of second messengers within the target cells that convey these signals to the genome or other cellular compartment. Each of these steps can be regulated by developmental programs and by the local milieu of nutrients and other hormones.

The body-wide endocrine system, however, is also an integrating system that is superimposed on multiple local regulatory systems that employ paracrine modes of regulation.[5] Paracrine control refers to the release by cells of soluble messengers that act on neighboring cells of another type. A circulation is not required because only physical proximity and the presence of receptors are required for effect. In 1980, Sporn and Todaro[6] added the concept of autocrine control to include the substances that cells secrete to regulate their own growth. Although autocrine control was initially thought to be a mode of growth control for neoplastic cells exclusively, autocrine control also characterizes the growth and function of many normal cells. Examples of autocrine control include the release of epidermal growth factor (EGF) by ulcerated gastrointestinal (GI) mucosa and release of transforming growth factor-alpha by normal intestinal epithelial cells.[7] As a consequence of the narrow range of action within the extracellular space of autocrine and paracrine growth factors, their roles in cellular regulation are much more difficult to document in clinical situations. It has recently emerged that proteolytic events at the cell surface are critical regulators of the accessibility of autocrine and paracrine factors to their receptors.[8] Multiple proteases associated with extracellular matrix or cell membranes are known to solubilize and activate growth factors from their cell surface anchored, but biologically inactive, precursors.

It has been proposed that growth factors can exert biologic actions without release into the extracellular space. *Juxtacrine* control refers to the actions of growth factors that remain anchored to the plasma membranes of the cells that produced them; cell-to-cell contact brings them into contact with receptor-bearing target cells.[9] Finally, some growth-

regulatory molecules can activate receptors on intracellular membranes including those in the cytoplasm, the nucleus, nucleolus, or mitochondrion, a mode of action called *intracrine* control.[10] In some instances, intracrine factors originate within their target cell and in other instances they are internalized from the extracellular space. Intracrine action appears to be critical for the regulation of the chicken ovalbumin gene.[11] In conjunction with the neuroendocrine mode of regulation, which makes use of axons to direct regulatory neurotransmitters to their target cells, the multiple systems of cellular regulation provide a diversity of regulatory options, each of which has relevance to an understanding of nutritional influences on growth. The characteristics of endocrine, paracrine, autocrine, juxtacrine, intracrine, and neuroendocrine modes of regulation are summarized in Table 21-1.

TABLE 21-1 Modes of Cellular Regulation

Mode	Agent	Source	Vehicle	Target	Modul
Endocrine	Hormone	Gland	Circulation	Heterologous tissue	Neurons Hormon Growth
Paracrine	Growth factor	Local site	Diffusion	Heterologous cell	Hormon Growth
Autocrine	Growth factor	Local site	Diffusion	Autologous cell	Hormon Growth
Juxtacrine	Growth factor precursor	Local site	Cell contact	Adjacent cell	Proteas
Intracrine	Hormone Growth factor Nutrient	Intracellular	Cytoplasm	Intracellular receptor	?
Neuroendocrine	Neurotransmitter Growth factor	Neuron	Axon	Heterologous tissue	Hormon Growth Neurons

In addition to the protein and steroid molecules that comprise the classic hormones of the endocrine system, locally acting substances, often designated “growth factors” are the principal agents of the paracrine, autocrine, juxtacrine, and intracrine systems.[12] The distinction between hormones and growth factors is generally a functional one. There are instances in which a substance may be released from a gland into the circulation to act as a hormone at a distant site, whereas within a highly specialized tissue the same substance might be locally secreted as a growth factor to influence the function of adjacent cells. In many instances, nature

has retained the basic structure of successful regulatory molecules and, through a divergent evolution, has created new uses for them. The structural homology of insulin and the insulin-like growth factors (IGFs), which are discussed later in this chapter, illustrates how a substance with predominantly nutrient transport-regulating properties, which is found in even primitive unicellular organisms, has evolved to regulate highly differentiated functions.

Nutrients and the Growth of Cells

Holley[13,14] was among the first to propose that the intracellular availability of nutrients is the ultimate regulator of cell growth. He postulated that when cellular nutrition is adequate, mammalian cells require no additional extrinsic growth-promoting substances and that hormones and growth factors regulate tissue growth ultimately by altering the availability of nutrients. In the laboratory, the growth of cells and tissues clearly requires the proper combinations of hormones and growth factors in addition to an adequate supply of nutrients. There is ample evidence that growth factors and hormones influence the transport and utilization of nutrients by cells.[15–19]

Hormones and nutrients interact in a delicate balance: hormones alter the nutritional requirements of cells, and conversely, nutrients alter cellular hormonal requirements. McKeehan and McKeehan[20,21] found that cultured human lung fibroblasts require lower concentrations of various minerals and substrates in the culture medium as the concentration of serum growth factors is increased. Conversely, they found that adequate concentrations of nutrients reduce the need for growth factors, an interaction that has been systematically probed.[22,23]

Although adequate supplies of nutrients are necessary to allow full manifestations of the effects signaled by hormones and growth factors, hormones influence cell growth by mechanisms other than changing their cellular nutritional status. Thyroid and steroid hormones, for example, can change cell function by directly influencing the transcription of target genes in the nucleus, although adequate “nutrition” in the form of high-energy phosphates and other low-molecular-weight substrates is required for full manifestation of the signal. In contrast, most polypeptide hormones and growth factors bind to cell-surface receptors, and their ability to influence the genome requires the initiation of a cascade of reactions that involve lipids, proteins, and ions as second messengers. Specific micronutrients, such as glutamine, allow the amplification of growth factor

signaling, and individually activate intracellular signaling kinases (e.g., mitogen-activated protein kinases) in intestinal and liver cells.[24,25] Furthermore, there are amino acid response elements in the promoter of nutritionally important genes. One gene regulated by amino acid deprivation and the endoplasmic reticulum stress response is asparagine synthetase. Asparagine synthetase is recognized as a target of antileukemic chemotherapy and is essential for maintenance of cell viability.[26]

Nutrients and the Growth of Tissues

The study of cellular proliferation in the laboratory culture dish can provide information on the hormonal and nutritional needs of dividing cells, but the growth and development of the organism as a whole require that the enlargement and maturation of each tissue occur at appropriate rate and in proper sequence.[27] As they can influence nutrient requirements of individual cells, hormones can also affect the nutrient needs of complex tissues as well as the supply of nutrients in the fluid milieu in which they are bathed. The effects of a given hormone on its various target tissues can be quite different: catabolic in one tissue, anabolic in another (Table 21-2). These effects are generally not without coordination, as catabolism in one tissue can serve to increase the supply of nutrients to another tissue that is rendered anabolic by the same hormone. For example, under normal circumstances, anabolic hormones increase the protein content of both viscera and muscles.[28] In the nutrient-deficient state, however, anabolic agents such as growth hormone (GH) and androgens continue to preferentially support carcass protein (muscle) synthesis even at the expense of visceral protein. Androgens, for instance, diminish the rate of muscle breakdown in fasted guinea pigs, while accelerating the loss of protein from the liver.[29] Similarly, the weight loss of food-restricted swine can be reduced by the administration of GH, but the effect is to preferentially retain muscle mass, while depleting body fat.[30] Similar effects are seen in humans (see below) and have led to abuse of GH by competitive athletes. Conversely, an important adaptive response to long-standing malnutrition is a generalized inhibition of anabolic systems, such as those involving GH, estrogens, and androgens, in order to conserve essential body compartments.

TABLE 21-2 Actions of Hormones on Body Compartments

Hormone	Protein	Carbohydrate	Fat

Glucocorticoid	Breakdown in muscle, synthesis in viscera	Permissive for gluconeogenesis, glycogen synthesis	Redistribution
Insulin	Synthesis in muscle and liver	Glycogen synthesis in liver, glycolysis	Lipogenesis, inhibits lipolysis
Growth hormone	Synthesis in muscle	Insulin-like effects (acute), insulin antagonistic (chronic)	Lipolysis, inhibits lipogenesis
Thyroid hormone	Synthesis in liver, breakdown in muscle	Glycogenolysis, gluconeogenesis	Lipolysis
Androgen	Synthesis in muscle and viscera	Increased insulin sensitivity[31,32]	Redistribution[33]

Source: Adapted from Eisenstein and Singh.[34]

Although anabolic hormones preferentially preserve muscle mass when nutrients are in short supply, catabolic hormones serve to protect the viscera. Brief exposure of rats to glucocorticoids or to thyroxine increases the protein and glycogen content of the liver, whereas the protein content of muscle is depleted.[28] These effects are direct ones on hepatic uptake and synthetic processes and not merely the result of increased substrate availability from the carcass.[35] Even a prolonged exposure to glucocorticoids, which depletes both viscera and muscle, reduces visceral mass proportionally less than muscle while increasing adipose mass.

Critical Periods in Tissue Growth

The ability of tissues to recover from a nutritional insult varies greatly at different times during development. The study of normal tissue growth has provided a model of normal tissue development that has been used to analyze the variable effects of malnutrition at different developmental stages. As the organ or tissue approaches its predetermined complement of cells, the organ grows by increasing both its cell number and the size of each cell. When the adult complement of cells is attained, cell division ceases and tissue growth results totally from enlargement of existing cells.[36] Between these two periods, tissue growth appeared to result from both cellular hyperplasia and hypertrophy.

McCance[37] and Widdowson[38,39] performed studies on growing animals that clearly established the existence of critical periods of sensitivity to the effects of malnutrition. They manipulated the litter size and, therefore, the milk supply of rat pups during suckling and observed their subsequent growth. Rats that were nutritionally deprived during this

period were small, and their growth could not be restored by institution of normal food intake.[40] The mechanism for this runting appears to be an irreversible effect of undernutrition on the number of cells. Similar mechanisms are likely to operate in some forms intrauterine growth retardation in children, although the irreversibility of the growth deficit has come into question. About 85% of infants born small for gestational age (SGA) will exhibit catch-up growth in the first 2–3 years of life, but a small group has a high risk of short stature in adult life. It has been demonstrated that irrespective of basal GH secretory status, GH treatment can accelerate growth in SGA children, and lead to normalization of adult stature.[41]

Winick and Noble[42] provided further evidence that the nutritional state of the neonatal period influences cell proliferation and consequently determines the ultimate size of the animal and its organs. Food restriction in the first 21 days of life produced a subnormal complement of cells in most tissues. However, the size of the cells was normal. Adequate nutrition after weaning could not restore normal growth, presumably because of an irreplaceable deficit of cells. Food restriction between 21 and 42 days resulted in a comparable stunting of growth in most tissues, but the brain and lung were able to resume normal growth with the restoration of proper nourishment. In these tissues, the total adult cell number had already been attained, and malnutrition produced a reversible decrease in cell size. When malnutrition was induced between 65 and 86 days, almost all organs underwent a reversible decrease in cell size only.

Growing tissues are as sensitive to an excess of nutrients as to a shortage. When rat litter sizes were reduced to provide supranormal nutrition, the offspring were larger than normal and were found to have hypercellular organs.[43]

As it has evolved from studies such as these, the critical period hypothesis proposes that abnormal nutrition, either excessive or deficient, during the phase of tissue growth by cellular proliferation, can increase or decrease the ultimate size of a tissue by enhancing or impairing cell division. These effects are irreversible because they bring the tissue into the phase of growth by cellular hypertrophy with an abnormal number of cells or abnormal organization. When nutritional surfeit or deficit occurs after establishment of the adult complement of cells, the net effect is a change in cell volume, but not in cell number, and is reversible by normalization of the nutrient supply. Because tissues mature at different rates, the long-term effects of nutritional variations occur most prominently in those tissues that are at a susceptible developmental

period.[44] An important example of this principle of "programming" following an insult at a critical, sensitive period of early life is that mothers who are malnourished during pregnancy often have infants with intrauterine growth retardation, subsequent growth retardation, and ultimately with disproportionately high rates of coronary heart disease, high blood pressure, and high cholesterol, during adult life.[45] Intrauterine growth retardation in girls has recently been linked to the development of hyperandrogenism, insulin resistance, and ovulatory dysfunction in adolescent years.[46–48]

Catch-Up Growth

Parents often want an estimate of their child's ultimate height. Mid-parental height combined with an assessment of skeletal maturity, or "bone age," is widely used to predict adult height and is probably its single best predictor.[49–52] However, in situations where the parents are either unusually short or unusually tall, the child can be relatively less short or tall, respectively—an observation called "regression to the median."[53]

Children have the remarkable capacity to accelerate their growth when recovering from a growth-impairing influence such as malnutrition or disease. At the complex level of organization that is required for statural growth, the ability of nutritionally deprived cells and tissues to be restored to functional health is reflected in the phenomenon of "catch-up growth," a term used by Prader and colleagues.[54] Subsequently, "catch-down" was coined to refer to the complementary process that follows removal of growth-accelerating influences, such as occurs with suppression of precocious puberty, restriction of food in obesity, or cessation of GH therapy in hypopituitary children.

Even under the most favorable circumstances, the accretion of height does not occur at a fixed rate, but is developmentally regulated. Gender-specific, nutritional, and—in some cultures—seasonal influences are also superimposed. The period of most rapid postnatal growth in children occurs in the first months of life, when length increases by 14–22 cm/y. By the second birthday, the mean growth velocity has slowed to about 8 cm/y, and to about 5 cm/y just before puberty. Then, under the influence of sex steroids (but involving the coordinated actions of GH, IGFs, thyroid hormones, and others), growth velocity doubles to 8–10 cm/y before statural growth ceases, as the epiphyses close.

After the second year of life and continuing throughout childhood, growth velocity is modulated to maintain stature at a constant position

relative to the general population. The height percentile attained by about 2 years of age is maintained faithfully throughout childhood and correlates well with the height percentile in adulthood.[55] Statural growth along a predetermined percentile on a growth chart is often called canalization. When growth-retarding or growth-accelerating processes disrupt canalization, growth curves will fall across channels. With amelioration of the abnormal condition, a compensatory acceleration or deceleration occurs to restore the original growth channel (Figure 21-1).

In the first two years of life, catch-up growth can be a normal adaptation in children whose birth size is at variance with their genetic potential. Although statural growth from age 2 to adulthood is primarily controlled by genetic influences, the determinants of body size during fetal life are largely determined by maternal and nutritional influences. The interval between birth and roughly 2 years of age is a preprogrammed period of catch-up or catch-down growth and is characterized by a shift of growth channels as maternal influences give way to genetically determined forces. It is essential for the clinician to be aware of these forces during this period because genetically programmed changes in growth velocity can be misconstrued as manifestations of disease.[56]

From a practical standpoint, for catch-up growth to be complete, the insult must be limited in duration and must not occur during certain vulnerable periods. Williams and coworkers[57,58] noted that the degree of catch-up growth is generally muted if it begins when growth is normally decelerating. On the basis of observations in birds and mammals, Wilson proposed that catch-up growth potential is modified by the nature of the insult, its severity, its duration, and the developmental state of the animal at the onset of the insult. For example, it had been assumed that GH deficiency and hypothyroidism were two conditions with the potential for essentially complete catch-up. However, the catch-up potential of hypothyroid children is diminished in proportion to the duration of the hypothyroidism before treatment.[59] The subjects studied had been hypothyroid for approximately five years and had deficits from their predicted heights of 25 cm at the onset of therapy; however, at the conclusion of therapy an average deficit of 7 cm remained (Figure 21-2). The magnitude of deficit between final height and predicted height was in proportion to the duration of hypothyroidism before treatment began. Similar conclusions resulted from studies of children with GH deficiency of long duration before treatment.[60] Incomplete catch-up growth has also been documented in children with acute nutritional insults, such as diarrhea, when they are superimposed on a background of chronic

malnutrition.[61,62]

In addition to its duration, the specific nature of the insult may be important in determining the extent of catch-up because some growth-arresting conditions appear to cause irreversible changes. Mosier found that cortisone-treated rats failed to regain normal body size after cessation of treatment, whereas rats that were comparably stunted by fasting resumed normal growth when refed.[63] Cartilage from the steroid-treated rats had increased numbers of dead and dying cells, altered cell morphology, and alterations in the matrix. Despite these seemingly irreversible morphologic effects on chondrocytes, GH therapy has been shown to reverse many of the catabolic effects, increase anabolic ones, and promote growth in children with glucocorticoid-induced short stature.[64]

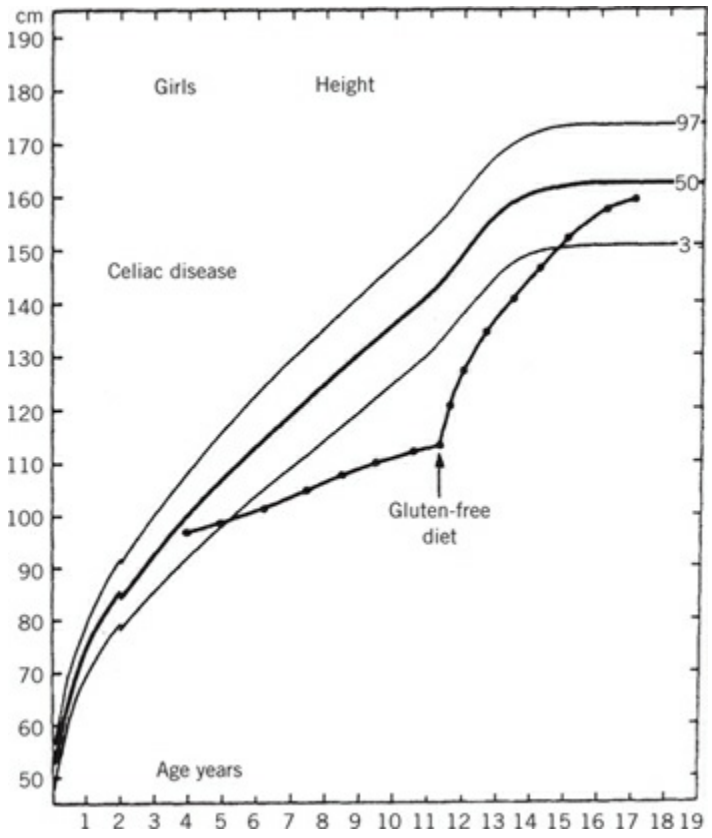

Figure 21-1 Catch-up growth in a girl with celiac disease. After eight years of growth failure, she was placed on a gluten-free diet and exhibited striking catch-up growth. Note return to previous growth percentiles. (Courtesy JM Tanner.)

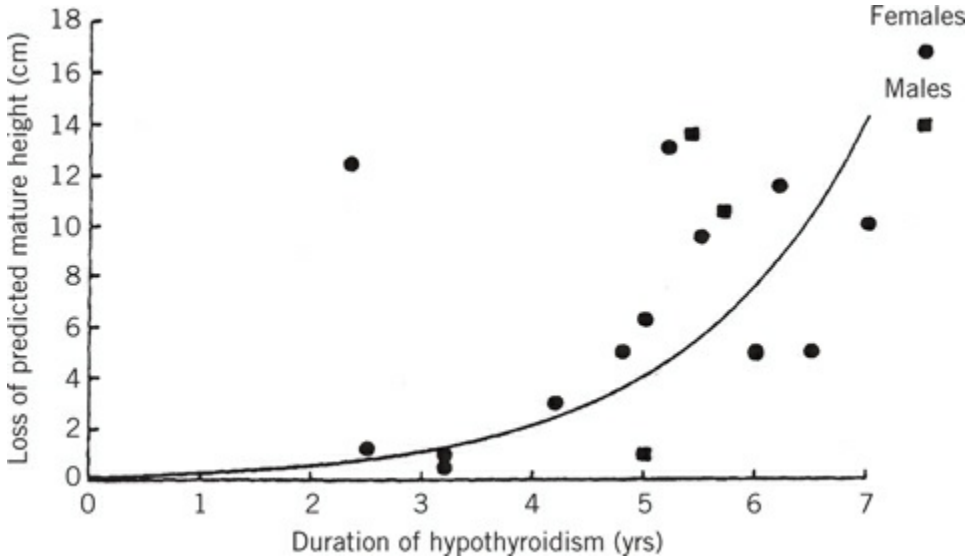

Figure 21-2 Loss of catch-up potential with long-standing hypothyroidism. Relationship between loss in adult height and duration of hypothyroidism before treatment in children. Loss of predicted height is predicted height at time of diagnosis minus actual mature height. Duration of hypothyroidism is chronologic age minus bone age at diagnosis. Adapted from Rivkees et al.[59]

It has been suggested that the catch-up growth of recovery from malnutrition in some experimental conditions is associated with an increase in the efficiency of energy utilization.[65] Fasted rats are capable of a fivefold increase in energy utilization efficiency for weight gain during recovery, perhaps by decreased thermogenesis.[66] The situation may be different in humans: children recovering from malnutrition often have increased appetite and caloric intake, suggesting to others that energy utilization is not efficient.[67] Some marasmic children do not begin to gain weight until 3–5 weeks of refeeding, despite an intake of more than 130 kcal/kg/d.[68] (chapter by Mary Penny in this textbook). In fact, once the infant is resuscitated with respect to fluid balance, infection therapy, glucose control, and temperature control, they usually require between 150 and 220 kcal/kg/d to gain weight.[69]

Implied in the concept of catch-up or catch-down growth is an ability of the organism to constantly monitor its size and determine the extent of deviation from the intended size; to alter its velocity when unrestrained from the growth-perturbing influence; and finally, to again modulate its altered velocity to prevent overshooting or undershooting the channel.[70–73] Williams stressed the theoretical importance of distinguishing between

catch-up growth and compensatory growth.[73] He recognized that the former involved growth to attain a projected (and moving) statural target, whereas the latter involved the growth of a tissue or organ to restore actual lost mass as in the regeneration of liver following a partial hepatectomy.[74]

Two divergent, but not necessarily exclusive, models have been put forward to explain the ability of the organism to monitor body size and initiate catch-up. Tanner[75] postulated the existence of a "sizostat" in the central nervous system (CNS) that maintained communication with the peripheral tissues. Along the same lines, Leibel[76] proposed that the concentration of a circulating hormone, such as insulin (or its ratio to other hormones or metabolites), might reflect the size of a body compartment, such as the adipose mass, by monitoring the number of insulin receptors on adipocytes. With the isolation of leptin, the data that support a neuroendocrine control of weight regulation have been far stronger than that of a neuroendocrine control of statural catch-up. For example, to initiate catch-up growth in conditions of malnutrition, the child must attain a body weight that is 85% of the normal weight for height.[77] The interactions between adipose mass and the CNS are discussed in the section on Reproductive Function in Malnutrition.

In contrast to a neuroendocrine mechanism of catch-up growth, Baron and colleagues[78] focused on the growth plate as the key tissue in catch-up growth. Their data showed that a unilateral growth-suppressing influence, accomplished by transient administration of glucocorticoids to a single growth plate, was accompanied by catch-up growth acceleration at that growth plate only, not systemically.[79] Although their model does not preclude the involvement of systemic hormones and the CNS, they proposed that growth-inhibiting conditions decrease proliferation of growth plate stem cells, thus conserving their proliferative potential. Catch-up growth results from a putative clock, or time tally to use Tanner's term, within the stem cell compartment.

Although it is likely that both systemic (neuroendocrine and endocrine) and local (paracrine, autocrine, and juxtacrine) signals will be implicated as critical regulators of the proliferation that occurs during catch-up or catch-down growth, there is little evidence to date that hormones and growth factors are significant mediators of the catch-up phenomenon. These data are extensively reviewed in reference 77.

GH, IGFs, AND INSULIN

Normal Growth

GH and IGFs in Normal Growth

Growth hormone or somatotropin is essential for normal, balanced somatic growth from childhood to normal adult stature. Growth hormone deficient children are not only short but have profound deficits in lean body mass and excess adipose tissue in addition to abnormalities in glucose homeostasis. The mechanism by which this process is regulated is incompletely understood, especially in the fetus. The actions of GH involve a complex interaction among GH genes, GH receptors, IGFs or somatomedins, IGF receptors, and IGF-binding proteins (IGF-BPs). In addition, the GH–IGF axis is entwined in a regulatory web that is strongly modulated by nutritional signals.

IGFs and the Somatomedin Hypothesis

With the advent of techniques for the culture of tissues and cells in the laboratory almost 50 years ago, it became evident that few of the biochemical events that had been attributed to GH in vivo could be reproduced in isolated tissues. These included effects on chondrocyte proliferation and sulfate incorporation into glycosaminoglycans of growth plate cartilage. These observations led Salmon and Daughaday[80] to propose the “somatomedin hypothesis”: that the growth-promoting effects of GH are not direct ones on its target tissues, but result indirectly from the actions of a “mediator” substance under GH control. Reviewed in reference 81, initially called sulfation factor or thymidine factor, based on the assay system used to detect its presence, it was later determined that these two biological activities resided in the same molecule, which was renamed somatomedin.[82] Other somatomedin species were initially proposed, but somatomedin-C (Sm-C) was determined to be the GH mediator present in serum.

IGFs were purified in parallel, but independent, studies to characterize the source of the insulin-like biological activity of serum, only a small part of which derives from insulin itself. Two molecules were identified, IGF-I and IGF-II, the amino acid sequences of which were found to be remarkably similar to proinsulin.[83,84] Sm-C is identical to IGF-I, and current convention prefers the IGF terminology, although a number of IGF-I assays available from clinical reference laboratories retain the Sm-C designation. The properties of IGF-I and IGF-II are contrasted in Table 21-3. Although the current nomenclature has the disadvantage of dissociating the IGFs from their regulatory link with GH, it does more firmly root these

substances in the realm of nutritional control.

Initial iterations of the somatomedin hypothesis were inspired by endocrine models of growth control: liver was found to be a major producer of somatomedin activity, and the paradigm that evolved had the liver functioning as an endocrine gland under the control of pituitary GH to secrete somatomedins whose ultimate target tissue was the growth plate. To further support an endocrine model, IGFs were found to feed back to the pituitary and inhibit the release of GH.

However, in the 1980s it became clear that multiple tissues express mRNA for IGFs and are involved in IGF production.[85,86] Most compelling was the observation that IGF-I mRNA is expressed in perichondrium and periosteum, suggesting that local production of IGFs in the epiphysis might account for the growth stimulating effects of GH. Indeed, Isaksson[87] had shown that GH elicits an increase in both IGF-I mRNA and protein in rat epiphyses. On the basis of analogy to the work of Greene and colleagues[88] on the role of GH in the differentiation of adipocytes, Isaakson and colleagues proposed that GH stimulates the differentiation of chondrocytes in the germinal zone of the growth plate. Once the stem cells become chondrocytes, their proliferation would result from local (autocrine/paracrine) production of IGF-I.[87] However, inconsistencies remain among the data: GH- or growth hormone receptor (GHR)-deficient mice and humans have no paucity of differentiated chondrocytes, and growth plate chondrocytes can proliferate normally without IGF-I.[81] Nonetheless, the consensus is that locally generated IGFs in the epiphysis are the critical regulators of linear growth.

TABLE 21-3 Insulin-Like Growth Factors

Property	IGF-I	IGF-II
Synonyms	Somatomedin C, basic somatomedin	MSA, neutral somatomedin
Chromosome location	12	11
Molecular weight	7649	7471
Serum concentration	193 ± 58 ng/mL	647 ± 126 ng/mL
GH dependence of serum concentration	+++	+
Insulin-like actions	+	+++
Mitogenicity in cultured cells	+++	+
Developmental role	Postnatal	Fetal
Sensitivity to undernutrition	+++	±

GH, growth hormone; MSA, multiplication stimulating activity.

The weakness of the original somatomedin hypothesis was most clearly illustrated by the creation of a liver-specific knockout of the IGF-I gene. Using Cre/loxP technology, LeRoith and colleagues produced mice with hepatic IGF-I mRNA levels reduced to less than 1% of normal, resulting in a 75% reduction in serum IGF-I.[89,90] Nonetheless, these mice lacking hepatic IGF-I grew normally, and "there were no phenotypic distinctions between the liver-specific IGF-I gene-deleted animals and their wild-type littermates."[81] While these studies do not confirm that bone-derived IGFs are the critical determinants of linear growth, they do support the contention that circulating IGFs are not critical to skeletal growth. As expected based on their markedly reduced serum IGF-I levels, the liver-specific IGF-I knockout animals had elevated concentrations of GH, leading LeRoith to speculate that the major role of circulating IGF-I might be to modulate GH secretion.

IGF-BPs

In contrast to GH, which circulates in association with a fragment of the GH receptor called the GH-binding protein (GH-BP), IGF concentrations in blood are maintained at relatively stable levels by serum binding proteins that markedly delay IGF clearance. IGF binding in serum and other fluids resides in six different molecules, collectively known as the IGF-BPs. The IGF-BPs are summarized in Table 21-4.[91] The major IGF binding complex in serum consists of IGF-BP3 in association with the acid-labile subunit (ALS). IGF-BP5 can also interact with ALS and IGFs in the serum. Circulating IGF-BP3 concentrations, such as those of IGF-I, are GH dependent. It is now clear that many, if not all, of the so-called somatomedin inhibitors identified in early bioassays of somatomedin activity, especially in conditions of malnutrition and disease, were actually IGF-BPs.

All six proteins have higher affinity for both IGF-I and IGF-II than do IGF receptors. IGF-BPs were initially proposed to function as IGF-sequestering agents, thus limiting the concentration of free IGFs. However, IGF-BPs modify IGF actions in a variety of ways. They transport IGFs across vessel walls and capillary membranes, they regulate the concentration of IGFs in the vicinities of specific tissues and cell types, they control IGF interaction with cell-surface IGF receptors, and at least three of these molecules (IGF-BP1, BP3, and BP5) can augment IGF action. Duan has proposed that a binary complex of a single IGF-BP and

IGF-I, which can leave the circulation rapidly, facilitating access of IGFs to their receptors, whereas a ternary complex consisting of IGF, IGF-BP3 (or BP5), and ALS cannot cross the endothelial barrier and remains in the circulation to sequester free IGF-I.[91] The implications of this on nutritional regulation of IGF action are discussed below. As noted in Table 21-4, serum concentrations of the three principal IGF-BPs are profoundly influenced by nutritional signals (mediated by insulin) and by GH. IGF binding and action can also be modulated by posttranslational modifications of the IGF-BPs such as phosphorylation, proteolysis, and matrix association.[92] Three of the IGF-BPs appear to be able to influence cell function independent of their role as an IGF-BP. For example, IGF-BP3 can inhibit proliferation in cells that have no IGF receptors.[93] Specific cell-surface receptors for the IGF-BPs have been proposed, and IGF-BP3 may have direct effects in the nucleus by interacting with the retinoid X receptor α (RXRα).[94]

GH, IGF, and IGF-BP Genes

In humans, GH is encoded within a cluster of five structurally similar genes on the long arm of chromosome 17.[95] These genes include the so-called normal GH gene (GH-N or GH-A), a variant GH gene (GH-V or GH-B), and three genes for placental lactogen (chorionic somatomammotropin). Only GH-N is translated into GH in the pituitary gland, and the other four genes of the family are expressed in placenta. Two distinct forms of GH result from differential splicing of the mRNA that is transcribed from the GH-N gene. The predominant product is a single chain of 191 amino acids with a molecular weight of 22 kDa. The product of alternate splicing of the GH-N gene is 20-kDa GH, which results from a deletion of 15 amino acids and comprises about 10% of circulating GH. Clear evidence for a differential regulation of the secretion of these two GHs is lacking, although they may differ in some of their biologic actions.

TABLE 21-4 Insulin-Like Growth Factor-Binding Proteins

Property	BP-1	BP-2	BP-3	BP-4	BP-5	BP-6
Molecular weight	25,000	33,000	54,000	24,000	31,000	30,000
Chromosome location	7	2	7	17	5	12

Serum concentration (nM)	0.8–2.8	6.1–18.3	60.170	Present		Present
Tissue localization	Serum, amniotic fluid, kidney, reproductive tissues	Serum, CSF	Serum	Serum, CNS	Placenta, kidney, bone, thyroid	Serum, CSFs
Regulation by GH	↓—	↓—	↑↑—			↑—
Regulation by Insulin	↓↓—	↓—				
Proposed function	Transport of IGFs from vascular space; immediate early gene	Transport of IGFs from vascular space	Major component of 150-kDa serum IGF complex intravascular reservoir	Blocks IGF action in cells	Potentiates IGF action in cells	

Each of the IGFs is encoded by a separate gene, although alternative splicing of each of the genes and other posttranscriptional modifications result in multiple IGF mRNA species. The extent to which the modification of IGF gene transcripts is important in the regulation of IGF action is unclear. The IGF-BPs as well arise from a gene superfamily that includes proteins whose function and relationship to IGF physiology are as yet undetermined.[96]

GH–IGF Axis: Physiologic Regulation

Pituitary GH release is regulated by two principal hypothalamic peptides, one stimulatory (GH-releasing factor, GRF or GHRH) and one inhibitory (somatostatin, SRIF) (Figure 21-3). Blood concentrations and patterns of GH secretion result from an interplay between these two substances on the somatotropes of the anterior pituitary. The hypothalamus receives rich innervation from higher centers in the brain, providing a mechanism by which even emotional influences can alter GH secretion (see discussion of “psychosocial dwarfism” later in this chapter). However, other modulating influences on GH release have been identified. Both free fatty acids and the orexigenic (appetite-stimulating) neuropeptide Y are known to directly inhibit GH secretion, whereas the fat-derived hormone, leptin (see below) stimulates GH release, perhaps by inhibiting secretion of neuropeptide Y.[97–101] Very recently, ghrelin has come to the fore as a potent regulator of

GH secretion, food intake, and fat mass. Ghrelin levels surge before every meal, and ghrelin injections rapidly stimulate food intake. Levels are very high in ravenous Prader–Willi patients and are low after gastric bypass.[102] Investigators studying a family of synthetic GH-releasing peptides, the GHRPs,[103] identified a novel CNS receptor for these peptides and then identified ghrelin as its natural ligand. Ghrelin is produced by hypothalamic neurons and by a highly specialized population of endocrine cells in the fundus of the stomach, where its secretion is suppressed by food intake. The model that is emerging ties stomach-produced ghrelin to the nocturnal stimulation of GH secretion, while hypothalamic ghrelin regulates food intake.[104]

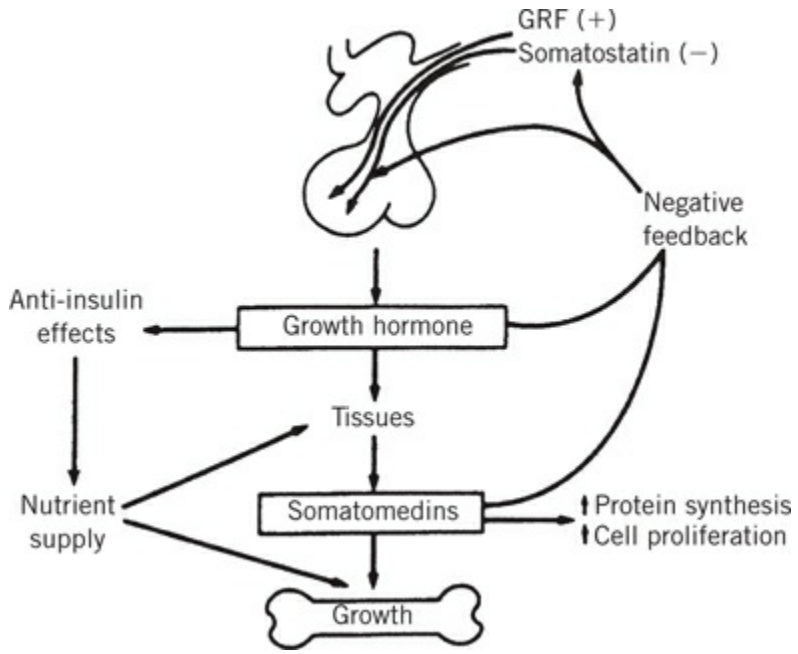

Figure 21-3 The growth hormone–somatomedin axis. (+) stimulatory action; (−) inhibitory action.

Peripherally produced IGFs feedback to inhibit GH secretion by the pituitary. IGF-I can stimulate the secretion of somatostatin by the hypothalamus[105] and may also directly inhibit GH synthesis.[106] It remains to be clarified whether IGFs of peripheral or hypothalamic origin are responsible for the inhibition of GH secretion, but the observations previously cited of enhanced GH secretion in the liver of the IGF-I knockout mouse suggest that circulating IGF-I is a prime regulator of GH

secretion.[89]

In response to GH, but modified by other hormones and most critically by nutritional factors, multiple tissues in the body synthesize and secrete IGFs. Although the liver is the major producer of circulating IGFs, its primacy in the GH–IGF axis has been supplanted. Multiple cell types in virtually every tissue examined from both fetus and adult can synthesize IGFs. Thus a model of IGF action has evolved that is primarily a paracrine one in which IGFs are produced in multiple tissues and act on target cells in the vicinity of the producing cells. Thus the function of the large quantities of circulating IGFs is not clear, but they may be more important for their insulin-like effects on metabolism than on their mitogenic effects.

GH and IGF Concentrations in Blood

Although it was believed that GH circulates in the blood free of binding proteins, it is now recognized that between 25% and 35% of circulating GH is loosely complexed to a 60-kDa glycoprotein referred to as the GH-BP.[107] This protein is identical to the extracellular domain of the GH receptor, but it is unclear whether in humans GH-BP arises from alternative splicing of the GH receptor mRNA, as it does in the rat, or is shed from cell-surface receptors by peptidases. Changes in serum concentrations of GH-BP reflect changes in the number of cell-surface GH receptors.[108] In contrast to the prolonged half-life of IGFs bound to the IGF-BPs (more than 12 hours), the plasma half-life of GH is about 20 minutes. Clinically, IGF-I concentrations in blood have been shown to reliably mirror the total GH secretory activity. Thus, in older children and adults who are well nourished and do not have hypothyroidism, serum IGF-I measurements are more useful than random measurements of GH in diagnosing conditions of GH deficiency (hypopituitarism) or excess (gigantism or acromegaly). The marked influence of nutritional status on IGF production is discussed later in this chapter.

GH secretion in humans is highly episodic. Blood concentrations are generally low or undetectable for much of the day and are interrupted by burst of secretion that results in high concentrations for roughly 90 minutes before returning to the low baseline. This pattern is developmentally regulated.[109] The number and amplitude of secretory episodes are small in young children. Under the influence of gonadal steroids, both the frequency and amplitude increase dramatically and reach their highest levels during puberty, especially during sleep; they then gradually decline over the ensuing decades.

The combined concentration of IGF proteins in the blood is on the order of 750 μg/L or 100 nM. Although GH remains the predominant regulator of IGF production and IGF-BPs, which are the principal regulators of bioavailable IGFs, a number of other hormones influence IGF-I concentrations in blood. IGF-I is low or nonexistent in fetal life, when IGF-II appears to be the predominant somatomedin. During fetal life, placental lactogen or the product of the GH-V gene is likely to be the major regulator of somatomedin production.[110] Prolactin, another GH-like hormone, can also stimulate the production of IGFs in cultured cells and probably in clinical conditions of prolactin excess. Blood levels of the IGFs remain low during infancy and early childhood but rise dramatically at puberty in response to increases in GH secretory activity. In addition, IGF-I concentrations are low in patients with hypothyroidism.[111]

Direct Versus Indirect Actions of GH: A Unifying Hypothesis?

GH initiates a signal by binding to specific receptors on the surface of target cells. A single GH molecule contains two separate receptor-binding domains, which facilitate the formation of receptor homodimers on GH binding.[112] Receptor dimerization is a feature common to a number of growth factor receptors and appears to be a prerequisite for signaling. When activated by ligand, the GH receptor dimerizes and associates with Janus Kinase 2 (JAK2). JAK2 then phosphorylates a family of proteins called signal transducers and activators of transcription (STATs). STAT proteins directly bind to DNA and directly regulate gene transcription. STAT target genes include those that encode a negative regulatory protein called suppressor of cytokine signaling-3 (SOCS-3).

The sequence of GH-initiated signaling events often extends to intracellular pathways that are activated or modulated by other hormones or growth factors, leading to complex intracellular interactions and diverse, but coordinated physiologic events. Among the targets of the activated GH receptors are insulin receptor substrate-1 (IRS-1) and IRS-2, which in turn recruit phosphatidylinositol-3 kinase (PI3-kinase) to the IRS-proteins. Activated PI3-kinase activates protein kinase B (PKB)/Akt, which in turn activates glucose transporters (GLUT4) and increases cellular glucose uptake. PKB/Akt can also activate phosphodiesterase 3B, which lowers cellular concentrations of cAMP, resulting in decreased phosphorylation of the hormone sensitive lipase and inhibition of lipolysis.[81,113]

The actions of GH in vivo have been categorized as either indirect (IGF-mediated) or direct ones. The direct actions vary significantly

depending on the duration of exposure. After short-term administration to GH-deficient individuals or to isolated GH-sensitive tissues in culture, GH has effects very much like those of insulin. They are rapid in onset, transient in duration, and not mediated through the actions of IGFs. They include the stimulation of glucose and amino acid transport and protein synthesis. GH also has inductive effects on a number of enzymes. In patients with GI and pancreatic disease who are taking parenteral nutrition (PN), administration of GH is associated with an increase in protein, potassium, and phosphorus balance.[114]

Chronic GH administration, in contrast, results in biochemical actions that appear antagonistic to insulin; blood sugar rises and fat mobilization and fatty acid oxidation occur. In fact, release of GH is one of the stress responses that the body uses to maintain euglycemia, while individuals with GH-secreting tumors can develop frank diabetes mellitus. About 3% of athletes take GH, often combining it with anabolic steroids. There is no conclusive evidence that GH enhances athletic performance, and an excess can cause acromegaly, myopathy, and hypertension. However, it does produce perceptible fluid shifts and reduced fat mass, increased lean body mass, resulting in a more “toned” appearance.[115] (PMID 23626006)

The origins of these paradoxical “direct” GH actions are not clear but may reside in the structure of the GH molecule itself. The 20-kDa variant has been reported to have only one-fifth the insulin-like activity of the 22-kDa GH molecule, while retaining normal growth-promoting and diabetogenic activity.[116,117] However, analysis of the biologic activities of both the 22-kDa and 20-kDa GH molecules in transgenic mice demonstrated largely overlapping activities with regard to linear growth and carbohydrate metabolism.[118]

The concept that IGFs can mediate the actions of GH in promoting linear growth has been validated by a number of studies that show that IGF-I injections increase tibial width and costal cartilage DNA synthesis in hypophysectomized rats to an extent that is comparable to that in GH-treated controls. In human newborn infants, umbilical cord plasma levels of IGF-I and leptin (see below) show a strong positive correlation with increasing birth weight and birth length.[119] Both IGF-I and leptin, which is secreted by both adipocytes and placenta, are important for fetal growth. The ability of IGF-I to stimulate linear growth in the absence of GH is strongly supported by studies demonstrating overgrowth in transgenic mice overexpressing IGF-I and in IGF-I-treated humans with Laron-type dwarfism, a condition that results from the hereditary absence of GH receptors. A recent study of 55 children with idiopathic short stature

revealed a lower basal level of IGF-I and a lower stimulated level of IGF-I, compared with normal body mass index controls, supporting the principle of an impaired somatotrophic axis. IGF-I receptor levels were unchanged.

IGF-I, IGF-II, and a truncated form of IGF-I, in addition to EGF, are also present in colostrum and in breast milk.[120] Importantly, intestinal IGFs are also locally produced by the mesenchymal cells within the lamina propria. Milk-derived IGFs appear to act on cells in the gut and do not have direct effects on somatic growth. However, by improving bowel function, they may increase nutrient absorption, thereby promoting somatic growth. The trophic effects of IGFs have generally been observed in the distal bowel (ileum) more than jejunum. In the piglet intestine, oral rhIGF-I increased small intestinal weight, protein and DNA content, and jejunal and ileal villus height.[121] In addition, oral rhIGF-I has been shown to increase intestinal sodium absorption and the maximal rate of glucose and alanine absorption in newborn piglets.[122]

When intestinal cells are studied, IGFs are well-known stimulators of cell proliferation[123] but also are potent stimulators of cell migration, a mechanism central to the healing of ulcers, villus damage in viral enteritis, and other lesions. The mechanism by which migration/restitution is stimulated appears to be dependent on protein kinase C.[124] However, other signaling pathways are activated by IGF-I, including the PI3-kinase pathway, c-Jun nuclear kinase, and mitogen-activated protein kinases.[125] Consequently, growth factors have been extensively investigated as therapeutic agents to enhance gut integrity and facilitate repair.

Orally administered growth factors have been found to exert trophic effects to the intestinal mucosa in experimental rotavirus diarrhea and in rats with short bowel syndrome.[126,127] In two studies, the combination of the primary metabolic fuel of the intestine, glutamine, with either systemic GH or IGF-I resulted in a synergistic trophic response.[128,129] A synergistic trophic response of glutamine with transforming growth factor-alpha was seen after ischemia/reperfusion injury of the porcine intestine.[130]

In viral enteritis, exogenous growth factors have enhanced mucosal mass without reducing diarrheal output or increasing specific activities of jejunal disaccharidase enzymes.[126,131] In short bowel syndrome and ischemic bowel disease, growth factors and the trophic amino acid L-glutamine have been shown to have synergistic effects.[132,133] These effects have not been translated into clinical therapy for diarrheal diseases to date, probably because of concerns about adverse events, including tumorigenesis.

Another disease for which enteral growth factor therapy has begun to be studied is short bowel syndrome. In this condition, which is the leading cause of intestinal failure in newborns, the infant's bowel length limits absorption, leading to a prolonged dependence on PN, which, in turn, can result in end-stage liver disease. In several studies, Donovan and colleagues[134] treated malnourished newborn piglets (given 80% of required calories via PN) with enteral IGF-I. They found that enteral IGF-I improved intestinal morphology and markedly increased disaccharidase activity in parenterally fed piglets when compared to those given partial enteral nutrition alone.[135]

Some notable differences between GH and IGF-I responses in the gut have further strengthened the concept that GH has both direct and IGF-mediated actions.[136] Transgenic mice overexpressing GH and IGF-I have increased body weight, as well as increased small bowel length and mass. However, GH had more profound effects on body mass compared to IGF-I (60% vs. 23% increase), while IGF-I had much greater effects on bowel length (44% vs. 20% increase). IGF-I but not GH overexpression increases intestinal crypt cell proliferation while reducing crypt cell apoptosis. In further support, murine knockout models of IGF-I, the GH receptor, or both show that both factors have major independent effects on somatic growth (30%–50%), while lack of functional expression of both growth factors profoundly affects growth. *IGF-I/ghr* double knockouts reach only 17% of the expected adult body weight.[137]

IGF-I and GH have not been to be beneficial in limited studies of humans with short bowel syndrome. On the other hand, a growth factor that has received considerable attention and that is consistently trophic in animal models is glucagon-like peptide-2 (GLP-2). Phase 3 trials have shown that a long-acting GLP-2 analog teduglutide stimulates mucosal growth, reduces malabsorption, and reduces PN dependence in adults with short bowel syndrome (23587733). Mechanisms of action include increasing blood flow and paracrine actions (because there are no GLP-2 receptors on enterocytes); teduglutide increases mucosal levels of IGF-I, epidermal growth factor, and keratinocyte growth factor.

Insulin in Normal Growth

The prominent influence of insulin on normal growth is best illustrated in disorders at the extremes of altered insulin secretion. Especially in the fetus, hyperinsulinemia produces somatic overgrowth. Hyperinsulinemic infants born to poorly controlled diabetic mothers or infants with hyperinsulinism of infancy[138] exhibit visceromegaly, increased body fat,

and increased length. Conversely, the hypoinsulinemic infant born with severe insulin resistance or pancreatic agenesis is small and depleted in body fat.[139] In postnatal life, poorly controlled diabetes mellitus can be associated with a striking growth failure, the so-called Mauriac syndrome.[140] The growth-promoting actions of insulin both in prenatal and postnatal life are complex and likely to result from both direct, largely metabolic, effects mediated through the insulin receptor and indirect, predominantly mitogenic effects mediated through the structurally homologous IGF-I receptor. Insulin mediates the feeding-stimulated enhancement of muscle and skin protein synthesis, but insulin is not related to feeding-induced stimulation of protein synthesis in the viscera.[141]

Insulin Receptor-Mediated Actions of Insulin

High-affinity insulin receptors mediate the rapid biologic actions of insulin in stimulating the cellular transport of substrates and in the induction of enzymes that promote glycogen and fat synthesis and that inhibit gluconeogenesis, lipolysis, and ketogenesis.

An indirect consequence of insulin action appears to be the stimulation of IGF production. A number of clinical studies have shown that the depressed IGF concentration associated with poorly controlled diabetes mellitus can be returned to normal with insulin therapy.[142] Insulin appears to directly stimulate IGF production in whole liver, liver slices, or cultured hepatocytes.[143] In addition, insulin may regulate IGF production by influencing the number of GH receptors on important IGF-producing tissues. In poorly controlled diabetes mellitus, there is a dramatic reduction in the number of somatogenic GH binding sites in liver. These can be restored to normal with insulin therapy.[144]

IGF Receptor–Mediated Actions of Insulin

In a few cell types, such as hepatocytes, certain teratocarcinoma cells, and mammary tumor cells, insulin appears to be directly mitogenic by binding to its own receptor at physiologic concentrations. However, some of the growth-promoting actions of insulin can be attributed to activation of IGF receptors. There are two principal IGF receptors, type 1 and type 2. The insulin receptor and the IGF-I receptor are homologous “heterotetramers,” consisting of two α and β subunits. The binding of insulin or IGFs to their respective α subunits activates a tyrosine kinase on the cytoplasmic portion of their respective β subunits. This kinase, in turn, transphosphorylates

tyrosines on the adjacent β subunit and on other cytoplasmic substrates that are essential for the actions of both insulin and IGF-I.[145] Both IGF-I and IGF-II can bind to and activate the insulin receptor, although with much lower affinity than insulin.

Crossover of IGF and insulin actions also occurs when type 1 IGF receptors are activated by insulin. Although type 1 receptors preferentially bind IGF-I, they can be activated by 10- to 100-fold excess concentrations of insulin, conditions that are achieved in some cases of hyperinsulinism, such as insulin-resistant states. Another level of overlap between IGF-I and insulin action is suggested by the finding that a single α, β subunit of the insulin receptor can associate with an α, β subunit of the type 1 IGF receptor, forming a hybrid tetramer.[146]

The IGF-II receptor is more enigmatic.[147] It preferentially binds IGF-II over IGF-I, but it is also the receptor that (at a different binding site) shuttles mannose-6-phosphate-containing extracellular proteins into lysosomes. The type 2 receptor does not contain an intracellular tyrosine kinase domain, and its role (if any) in intracellular signaling is unclear. Most of the actions of IGF-II are thought to be mediated through IGF-I or insulin receptors. IGF-II receptors do not bind insulin, but physiologic concentrations of insulin dramatically upregulate the number of these receptors on adipocytes.[148]

Insulin Synergy with Other Growth Factors

One further mechanism by which insulin appears to influence cellular growth is to alter the cellular requirements for mitogenic signals from other growth factors. As discussed previously regarding the interactions of nutrients and hormones, growth factor signals frequently converge on common pathways within a cell so that low concentrations of two growth factors can amplify the actions of one another. In cultured hepatocytes, insulin can potentiate the mitogenic signal of EGF or of vasopressin,[149] and in the well-studied BALB/c 3T3 fibroblast, the presence of insulin or IGF-I strongly modulates the mitogenic actions of EGF and platelet-derived growth factor.

Malnutrition

GH in Malnutrition

In humans, experimental fasting and malnutrition generally result in elevated serum concentrations of GH. Studies of malnourished populations in different parts of the world have often led to conflicting conclusions, in

part from differing criteria for malnutrition, from the inaccuracies inherent in characterizing complex GH secretory patterns from a single blood sample, and perhaps to some extent from confounding features such as infection.[150] The normal physiology of nutrient regulation of GH secretion is also complex; amino acids such as arginine stimulate GH release, whereas carbohydrates and fatty acids inhibit GH secretion. Clinical malnutrition results from a combination of dietary deficiencies that could be expected to have variable effects on GH release.

Recently, attention has turned to the effects of fasting on the pattern of GH release from the pituitary. As previously described, GH secretion in humans is episodic, and measurement of GH concentrations on random blood samples, as is typical of field studies, might be expected to give inconsistent results. Ho and coworkers performed frequent blood sampling (every 20 minutes) of fasted volunteers and uncovered an inherent pulsatility in GH secretion in humans that appears to be suppressed in the fed state, perhaps by the negative feedback of IGFs.[151] Over the course of a five-day fast, those authors measured significant increases in GH pulse frequency, maximal pulse amplitude, and 24-hour integrated concentration (Table 21-5). These changes coincided with a decline in concentrations of IGF-I and glucose and a rise in those of free fatty acids and acetoacetate. Subsequent studies led those authors to conclude that fasting-induced enhancement of GH secretion is mediated by an increase in GH-releasing hormone pulsatility and a decrease in somatostatin release.[152]

TABLE 21-5 Enhanced Pulsatility of Growth Hormone Release in Fasting

Measure of Pulsatility	Day 0[a]	Day 1[a]	Day 5[a]
GH peaks (number/24 h)	5.8 ± 0.7	7.3 ± 0.6**	9.9 ± 0.7*
GH peak amplitude (ng/mL)	5.9 ± 1.1	13.1 ± 1.2*	12.3 ± 1.6*
24-hour IGHC (μg/mL/min)	2.8 ± 0.5	7.8 ± 1.1*	8.8 ± 0.8**

GH, growth hormone; IGHC, 24-hour integrated GH concentration.

[a]Frequent venous sampling of six adult male subjects was performed during a control fed day (day 0) and during the first (day 1) and fifth (day 5) days of a fast.

*$P < .005$, compared with day 0; **$P > .0009$.

Serum GH concentrations are elevated in children with both kwashiorkor and marasmus[153–157] but do not allow distinction between the two. Becker and associates[153] observed the magnitude of GH elevation to be inversely related to the severity of protein malnutrition, as judged by

the serum albumin concentration. In their subjects, GH concentrations fell after feeding a protein-rich diet for 36–72 hours. The critical role of protein in the refeeding diet was also demonstrated by Pimstone and colleagues,[157] who found that refeeding with a high-carbohydrate, protein-free diet does not normalize GH concentrations. When caloric deprivation predominates, the GH response appears to be variable; some groups have reported depressed GH concentrations and others have reported GH elevations.[158,159] In short-term malnutrition, the adaptive benefits of elevated GH concentrations are suggested by the known direct effects of GH to increase gluconeogenesis, lipolysis, and fatty acid oxidation. Elevated GH concentrations might be expected to increase glucose production initially, while shifting the organism to a lipolytic, protein-sparing state.

Although short-term protein-calorie malnutrition is associated with elevated GH concentrations, long-standing malnutrition results in depressed GH secretion. Beas and coworkers[160] described a group of infants with low concentrations not only of GH but also of adrenal and thyroid hormones, suggesting generalized pituitary hypofunction. An adaptive function of a hypopituitary state in reducing metabolic activity had previously been proposed by Mulinos and Pomerantz,[161] who likened the malnourished state to a "pseudohypophysectomy."

Clinical Uses of GH in Disease States

GH signaling (as measured by IGF-I concentrations) is reduced in many conditions, including malnutrition, Prader–Willi syndrome,[162] thalassemia major,[163] type 1 diabetes,[164] leukemia,[165] and premature osteoporosis.[166] Also, Laron dwarfism, which results from inactivating mutations in the GH receptor, is characterized by dramatically reduced IGF-I concentrations.[167] The adaptive changes in GH release that accompany malnutrition have prompted a number of studies on the possible uses of GH in promoting anabolism during recovery from operation or injury. Clemmons and coworkers[168] determined the effects of GH injections on obese individuals subjected to hypocaloric diets. Although dietary restriction produced comparable weight loss in subjects receiving GH and those receiving placebo, those treated with GH (0.1 mg/kg every 48 hours) had a significantly lower daily nitrogen deficit than controls. Similar findings were reported by Manson and Wilmore,[169] who administered GH to volunteers receiving hypocaloric PN (Figure 21-4). GH therapy decreased the rate of weight loss and increased nitrogen retention. In

parenterally nourished patients recovering from GI surgery, GH administration has resulted in sustained nitrogen retention,[170,171] suggesting a possible role for this agent in promoting recovery from a variety of catabolic states.

Unfortunately, a series of investigations in critically ill adults with multiorgan system failure in several placebo-controlled, masked trials found that high-dose recombinant human GH treatment produced a twofold increase in mortality, increased the length of stay in hospital, and prolonged the duration of mechanical ventilation.[172] However, similar doses of GH administered to critically ill children with extensive body burns did not increase morbidity or mortality and reduced intravenous albumin and calcium requirements, compared to placebo-treated children. There were increased hyperglycemic episodes and insulin requirements in the treated group, although these were not considered dangerous.[173]

In an animal model of colitis (interleukin-10 knockout mouse), GH injections decreased disease activity, increased weight gain, and reduced apoptosis in the colon. The improvement was mediated by upregulation of a protein called SHP-2, which in turn reduced STAT-3 (see above) activation, while increasing the antiapoptotic protein bcl-2.[174] Similarly, administration or overexpression of IGF-I reduced inflammation and fibrosis in experimental ileocolitis[175] and in toxic hepatitis.[176]

In humans with several gastroenterological conditions, exogenous GH administration has been shown to have beneficial effects. In cystic fibrosis, GH treatment improved growth rate (linear and ponderal) and—by as yet undetermined mechanisms—reduced pulmonary exacerbations.[177,178]

Growth failure in the inflammatory bowel disease Crohn's disease is associated with small bowel involvement, Card-15 mutations, and mutations in granulocyte-macrophage colony stimulating factor (GmCSF). In addition, the liver cell-surface GH receptor is cleaved in the face of endotoxemia, a result of metalloprotease activation by LPS (18323468). In adults with Crohn's disease, a preliminary placebo-controlled trial of GH therapy for four months significantly improved the disease activity index score.[179] In children, inflammatory bowel disease activity was not influenced, but a four-month treatment with GH enhanced the lean body mass, decreased the fat mass, and enhanced linear growth velocity.[180] Denson's group has shown that in children with growth failure secondary to Crohn's disease, treatment with GH plus corticosteroid (compared to corticosteroid controls) was significantly more likely to produce a clinical remission and increased height velocity (PMID 20453679).

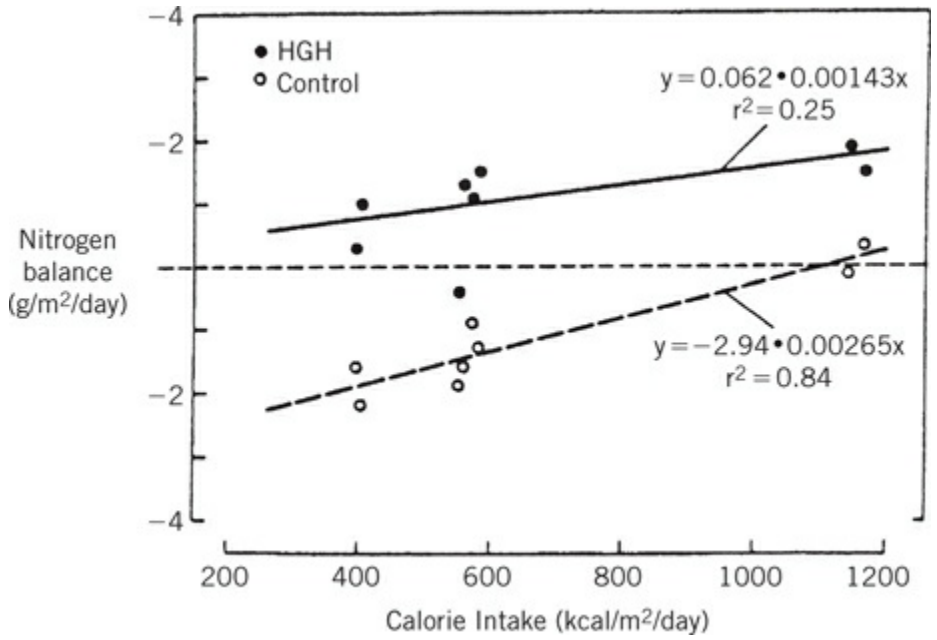

Figure 21-4 Positive nitrogen balance in growth hormone-treated subjects at all levels of hypocaloric calorie provision. Eight male subjects were exposed to various levels of hypocaloric intravenous feeding. Only adequate energy intake resulted in positive nitrogen balance in the controls (*open circles*), whereas growth hormone-treated subjects (*closed circles*) were in positive nitrogen balance at all levels of energy intake. Adapted from Manson and Wilmore.[169]

Substantial worldwide experimental support has emerged for GH treatment of infants born SGA, a condition also called intrauterine growth retardation (IUGR). This condition, highly prevalent in developing countries, is associated prevalent in developing countries, is associated with low body fat at birth, low IGF-I levels up to age 2, and subsequently abnormal catch-up growth characterized by increased adiposity, insulin resistance, and low-grade inflammation.[181] IUGR eventually tends to be associated with subsequently high rates of coronary heart disease, high blood pressure, diabetes, and high cholesterol.[182] Treatment of children manifesting IUGR with daily GH shots increased linear growth velocity in many studies, while delaying the onset of puberty and exhibiting few if any side effects.[183–187] However, treatment for years was required, higher doses were more effective, and younger children (3–5 years old) were more responsive to treatment.[188] Concomitant treatment with a gonadotropin-releasing hormone analog (to postpone puberty) and GH

resulted in increased height, lean body mass, and bone mineral density (PMID 23125290). Of major concern is the global scope of this problem with IUGR, however, because IUGR affects 20% of children in Malawi[189] and 25% of children in Pakistan.[190] Clearly, ethical problems will arise as to which children can be treated with this expensive and long-term therapy.

IGFs in Malnutrition

IGF Bioactivity, IGF Inhibitors, and IGF-BPs

Despite elevated GH levels in fasting or short-term malnutrition, the production of IGF-I is dramatically reduced in malnutrition. Studies using somatomedin bioassays were the first to indicate that serum IGF bioactivity falls with malnutrition. More recent data using highly specific radioimmunoassays indicate that the depressed bioactivity of serum from fasted or malnourished individuals results from a dramatic fall in IGF-I concentrations, minimal if any change in IGF-II concentrations,[191] and changes in IGF-BPs (Table 21-6).

Measuring serum somatomedin bioactivity in a sulfation factor assay, Grant and associates were among the first to show a nutritional influence on somatomedin activity[192]; they found low levels in the serum of malnourished South African children despite elevated GH concentrations. Those authors found both hormones to return toward normal by the ninth day of refeeding. Similar results using somatomedin bioassays were forthcoming from other malnourished populations,[193] including malnourished Thai[194] and Nigerian[195] infants and children and patients with celiac disease[196] and anorexia nervosa.[197]

Bioassays of IGF activity in blood, although relatively nonspecific as to which of the two IGFs is being measured, allow the detection of physiologically important IGF inhibitors in serum. Much of the older data on somatomedin inhibitors can be attributed to changes in the concentration of known IGF-BPs. Increased concentrations of inhibitors have been found in the serum of malnourished children and hypopituitary adults[193,198,199] and in serum from starved, hypophysectomized, or diabetic rats.[200,201] Salmon and colleagues[202] partially purified a 27- to 40-kDa, heat-labile inhibitor from fasted rat serum. Recent studies have suggested that this inhibitor may be the serum-binding protein, IGF-BP-1[203] (see Table 21-4). Serum concentrations of BP-1 almost double with fasting and decrease after meals.[204] In addition, they are elevated in diabetes,[205] consonant with the proposed role of insulin in the regulation

of BP-1 production. Phillips and associates have shown that concurrent with the fall in IGF activity of rat serum during fasting, total IGF inhibitor activity rises.[206] The IGF inhibitory activity of serum appears to be more nutritionally sensitive than the IGF activity itself. After six hours of refeeding, the IGF inhibitor activity had fallen significantly, but there was little change in IGF activity; both returned to normal with continued refeeding.

TABLE 21-6 Effects of Undernutrition on the GH–IGF Axis

Increased GH secretion
GH resistance in peripheral tissues
Decreased GH receptor mRNA
Decreased GH binding
Diminished postreceptor signaling (P)
Decreased somatomedin bioactivity
Decreased IGF-I production
Decreased IGF-I gene transcription
Diminished IGF-I mRNA stability (P)
Diminished IGF-I mRNA translation (P)
Normal IGF-II production
Increased IGF-BP-1 production
Decreased IGF-BP-3 production (P)
Increased IGF-I clearance
Increased IGF inhibitor production
Decreased tissue sensitivity to IGF-I

GH, growth hormone; IGF, insulin-like growth factor; IGF-BP, insulin-like growth factor binding protein; mRNA, messenger ribonucleic acid.

IGF-I and IGF-II in Malnutrition

As measured by specific radioimmunoassays, IGF-I concentrations drop dramatically with fasting in adult volunteers,[207] while those of IGF-II do not.[191] Clemmons found that fasting of overweight adult volunteers for 10 days produced a drop of IGF-I concentrations to hypopituitary levels; refeeding produced a return toward normal[207] (Figure 21-5). The decline in serum IGF-I correlated with nitrogen balance. In some physiologic circumstances, however, the fall in serum IGF-I concentrations becomes dissociated from the changes in nitrogen balance. Smith and coworkers[208] studied six conditioned athletes and concluded that strenuous exercise, which produces negative caloric balance, causes as much of a fall in serum IGF-I as does comparable caloric restriction without exercise, but a much lower nitrogen loss.

In contrast to the apparent insensitivity of serum IGF-II to fasting in adults,[191] Soliman and associates[209] have documented depressed IGF-II concentrations in children with severe marasmus and marasmic kwashiorkor. These levels returned to normal with refeeding. The magnitude of IGF-II depression was clearly not as great as that of IGF-I, and the IGF-II concentrations in sera of children who were underweight or had only kwashiorkor were not depressed. Thus, severe or long-lasting malnutrition in children may eventually depress IGF-II production, although IGF-I remains the more acutely sensitive to malnutrition. In addition, IGF-I levels may reflect imbalanced or abnormal nutrition. For example, infants with short bowel syndrome maintained on PN who developed liver disease had low levels of IGF-I.[210]

Serum IGF-I as an Index of Nutritional Status

The striking correlation between (as yet unidentified) aspects of nutritional status and serum IGF-I concentrations has led some investigators to suggest that the latter might provide a highly sensitive and quantitative way of following nutritional status. Clemmons and colleagues found that IGF-I increased by 170% over 10 days in six malnourished patients with GI disorders that necessitated either total parenteral or tube feedings.[211] All patients were in positive nitrogen balance when first measured on the second day of refeeding. Other commonly used indices of nutritional status, such as prealbumin, retinol-binding protein, and transferrin, fell much less dramatically and normalized much more slowly. Unterman and coworkers came to similar conclusions when they compared IGF-I concentrations with other indices in 37 generally elderly hospitalized patients with a variety of neoplastic, GI, and neurologic diseases.[212] The

IGF-I was more depressed than albumin or transferrin in patients who had no reduction in either triceps skinfold thickness or mid-arm muscle circumference. In six patients given nutritional support, IGF-I concentrations rose by more than 70% in each patient, while the lymphocyte count and transferrin concentration rose in only four patients and albumin concentration in only one. Serum IGF-I measurements have also been suggested as a means to follow the progress of children and adolescents with chronic inflammatory bowel disease.[213] In a study of critically ill patients, serum concentrations of prealbumin, retinol binding protein, and transferrin levels were strongly correlated with levels of IGF-I, IGF-II, IGF-BP3, and ALS.[214]

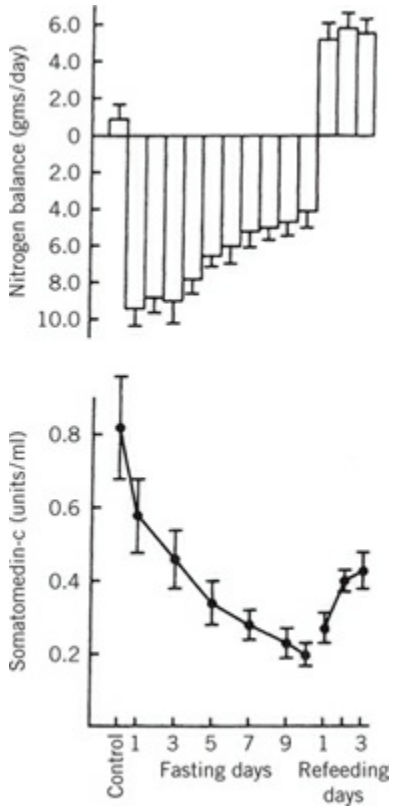

Figure 21-5 The effects of fasting on plasma somatomedin-C (IGF-I) and nitrogen balance. The subjects were seven males 20%–70% above ideal body weight. During the control period, they were fed a 1500 kcal diet for three days. Between days 4 and 13 they fasted, receiving only water, vitamins, and potassium chloride. Refeeding consisted of resumption of the control diet. Each point is the mean ± SEM. Adapted from Clemmons et al.[207]

Mechanisms of IGF Regulation by Nutrients

A number of studies have attempted to determine the specific components of the refeeding diet that regulate IGF-I production in recovery from an acute fast. When normal-weight human volunteers were fasted for five days and then refed with a normal diet, a diet that was isocaloric but protein deficient, or a diet deficient in both protein and calories, Isley and associates[215] concluded that intake of adequate quantities of both protein and calories is critical for the restoration of IGF-I after a fast. Animal studies have indicated that the roles played by protein and calorie intake in regulating serum IGF-I concentrations may be developmentally influenced. Prewitt and coworkers[216] placed 3-week-old rats on diets in which the protein content was varied (5%, 10%, or 15% lactalbumin) at one of three levels of energy intake (100%, 75%, or 50% ad libitum). After two weeks, protein intake played the major role in regulating IGF-I concentrations, whereas after nine weeks, both protein and caloric intake were important.

The malnourished state is one of resistance to the effects of GH. As noted previously, GH secretion increases in the fasted state, while serum concentrations of IGF-I fall. Merimee and colleagues found that GH administered to fasted, GH-deficient subjects induced a minimal increase in serum IGF-I concentrations in comparison with the 10-fold increase GH induced in normally fed, GH-deficient subjects. Studies in fasted[217–219] and diabetic[219] rats have correlated the fall in serum IGF-I concentrations with a decline in the number of hepatic GH receptors, suggesting that a primary effect of malnutrition, perhaps mediated by decreased insulin concentrations, is to decrease GH receptors and consequently IGF-I production. Indeed, fasting results in decreased GH receptor mRNA in the liver.[220,221] The situation may differ in protein-deprived rats, in whom a postreceptor defect in GH action has been suggested.[148] The net result of fasting is a decrease in the concentrations of IGF-I mRNA in the liver and other tissues.[220] This results from decreased transcription of the IGF-I gene, although the effects of protein deprivation may further influence IGF-I mRNA stability and also decrease the translation of IGF-I mRNA into peptide.[222]

The fasted or malnourished state is also one of resistance to the action of IGF-I. Thissen and associates[223] showed that, in contrast with normally fed, hypophysectomized rats, an infusion of recombinant IGF-I into protein-restricted rats did not stimulate an increase in weight gain or linear growth, despite restoring normal serum concentrations. Somewhat

surprisingly, this nutritionally induced IGF-I resistance does not result from a decrease in IGF-I receptors at target tissues; instead, most tissues show increased IGF-I binding.[224]

IGF-BPs in Malnutrition

Among the IGF-BPs, BP3 is unique in its diurnal rhythm that appears to be regulated by food intake. IGF-BP1 is rapidly suppressed following a meal, and it acutely rises in response to hyperglycemia. In this context, IGF-BP1 may serve as a glucose counter-regulatory hormone by further depressing free IGF concentrations in the hypoglycemic state. In addition to its regulation by nutrients, IGF-BP1 is stimulated by glucocorticoids and by cytokines such as TNFα and various interleukins. Nutritional status appears to also influence the phosphorylation status of IGF-BP1. Baxter has postulated that increases in IGF-BP-2, BP-4, and BP-6 during acute illness could serve to redistribute IGFs from ternary complexes in the serum to binary complexes in the extracellular space and make them more available to the tissues.[91]

Insulin in Malnutrition

With fasting or protein-calorie malnutrition, plasma insulin concentrations are reduced, although in some instances high and normal levels have been reported.[209] Some of these discrepancies might be explained by the observations of Lunn and associates[155] that in kwashiorkor there is an early phase of hyperinsulinism that is followed by insulinopenia. Diminished insulin release results in impaired tolerance to glucose or an amino acid load.[225] Pimstone and coworkers[226] noted that the insulin response to oral glucose is abnormal in malnourished children but that intravenous glucose elicits a normal response, suggesting that deficiencies of the so-called “incretins” may be important in determining the response to malnutrition. Those authors also demonstrated that the impaired insulin response to a glucose load in kwashiorkor could be ameliorated by the addition of potassium to the diet. The relationship of malnutrition and diabetes mellitus has been reviewed by Rao,[227] who concluded that a malnourished condition can influence the diabetogenicity of other agents, including dietary toxins, drugs, and viruses, but does not directly cause diabetes. In clinical practice, an initial presentation with malnutrition, dehydration, and hypoglycemia (<40 mg/dL) has been associated with a high mortality (>40%) for children with diarrheal dehydration.[228]

Psychosocial Growth Failure

The interactions of nutritional and hormonal influences have been extensively studied in cases of "psychosocial growth failure" or "deprivation dwarfism," terms used to describe the growth failure that can accompany severe emotional deprivation. Early in this century, it was recognized that emotional deprivation could be associated with growth retardation in institutionalized children.[229] Subsequent studies revealed that such children need not be in an institutional setting and that an impoverished emotional environment in the home is sufficient. Affected children have a voracious appetite with bizarre eating and drinking behavior such as foraging, drinking from the toilet bowl, and gorging. In addition, delayed speech, foul-smelling stools, a protuberant abdomen, and characteristic neurologic postures have been described.[229,230]

Patton and Gardner[231] speculated that emotional deprivation could produce growth retardation in a variety of ways, including failure of the care giver to provide adequate nutrition, depression-induced anorexia in response to the emotional environment, altered GI function, or changes in metabolism. Considerable attention has been paid to whether the growth failure and endocrine-metabolic changes of psychosocial dwarfism are the result of emotional deprivation alone or are secondary to impaired caloric intake.

A large body of evidence suggests that a hypopituitary state can develop in some children with emotional deprivation. Talbot found significant malnutrition in a group of 51 children with nutritional growth failure of no identifiable etiology and postulated that they might have "functional hypopituitarism"as a feature of "anorexia secondary to emotional disturbance.[132] Twenty years later, Powell and colleagues[233,234] studied emotionally deprived children and demonstrated diminished reserves of adrenocorticotropic hormone (ACTH) and GH, which were normalized when the affected children were removed from their adverse surroundings. The authors found little evidence of caloric deprivation in their patients and suggested that psychic factors caused their hypopituitarism. Miller and colleagues[235] demonstrated a loss of GH secretory episodes during a six-hour period of blood sampling in four children with psychosocial deprivation. In one child, GH secretion normalized after hospitalization and rehabilitation. Despite the apparent state of GH deficiency, attempts to induce growth in such children by administration of GH have been unsuccessful.[236,237]

Psychological factors were also invoked by Widdowson to explain her

observations on the growth of children in two German orphanages after World War II.[238] Orphans under the care of a stern and forbidding supervisor who chose meal times to rebuke the children gained weight at about one-third the rate of children at another, more hospitable orphanage despite comparable food intake. When the supervisor of the first orphanage was transferred to the second, the pattern reversed, and the new children under her care gained weight poorly.

A counter theme to the hypothesis of a strictly emotional etiology of psychosocial growth failure has been the suggestion that underfeeding by care givers is the primary cause of growth failure in these children. From their studies on emotionally deprived infants between 3 and 24 months of age, Whitten and colleagues observed dramatic weight gain in 11 of 13 children when the infants were given adequate nutrition in a hospital setting designed to reproduce the impoverished emotional ambience of their homes.[239] During a control period in which these children were fed equal amounts of food but also given a high level of mothering care, their weight gain was no greater. Other studies have found elevated fasting levels of GH in a number of infants and children with emotional deprivation, leading to the speculation that these infants suffered from food deprivation as well as emotional deprivation.[240]

Contemporary dietary and health misconceptions have created a modern-day version of the growth-retarded child from a turn-of-the-century foundling house or war orphanage. Pugliese and colleagues described a group of 14 adolescents who presented with short stature and malnutrition from self-imposed caloric restriction.[241] These children showed no evidence of overt psychiatric disease or anorexia nervosa but had restricted their food intake from a fear of obesity. Similar findings were reported in a group of younger children, 7–22 months of age, who presented with nutritional failure to thrive secondary to parental restriction of food arising from a fear of obesity, cardiovascular disease, or unhealthy eating habits.[242]

It is reasonable to propose from these somewhat disparate observations that the mechanisms involved in the growth failure associated with emotional deprivation form a spectrum (Figure 21-6). At one extreme are children in whom growth failure is nutritional in origin, whether from limited access to food, from emotionally induced anorexia, or from altered GI function. In these children, endocrine alterations are adaptive and occur in response to malnutrition. At the other extreme of the spectrum are those children whose hormonal and metabolic alterations are emotionally induced. The growth failure of these children is probably mediated by

hormone deficiencies rather than by inadequate nutrition. It would appear that many of the children with clinical features of psychosocial growth failure combine features of both extremes of the spectrum.

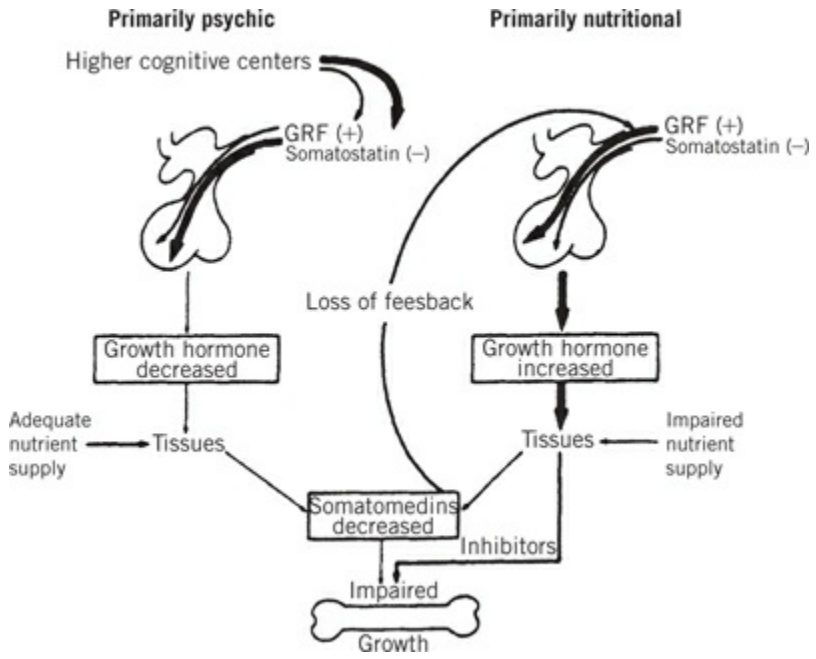

Figure 21-6 Psychosocial growth failure. Two possible mechanisms of psychosocial growth failure are proposed: primarily psychic (neuroendocrine) and nutritional. Under largely psychologic influences, pituitary growth hormone secretion is diminished in the face of normal nutrition (left). When undernutrition predominates, the endocrine changes observed are adaptive ones (right). Somatomedin production is reduced, IGF-binding proteins are increased, and growth hormone secretion is increased.

THYROID HORMONES

Thyroid Hormones and Normal Growth

The actions of the thyroid hormones, like those of insulin, can be broadly separated into directly metabolic ones and those that result from thyroid induction of other genes that regulate cell growth and function. Increased oxygen consumption, heat production, and accelerated metabolism constitute the allergenic effects of the thyroid hormones.[243] The mechanism by which thyroid hormones affect these actions is not clearly understood. Thyroid hormone signaling increases basal thermogenesis by

increasing ATP turnover and decreasing the efficiency of ATP synthesis. Decreased efficiency of ATP utilization has been linked to the generation of a proton leak across the inner mitochondrial membrane.[244] Unlike peptide hormones, which bind to cell membrane receptors and regulate cell function and gene transcription via second messengers, thyroid hormone receptors exist in the cytoplasm and directly regulate the transcription of other genes by binding to regulatory regions of DNA in the genome.[245] Many of the developmental effects of the thyroid hormones may result from induction of the genes for other hormones and growth factors, such as epidermal and nerve growth factors.[246]

Thyroxine (T4) is the major hormone secreted by the thyroid, but it is deiodinated at its outer ring to produce triiodothyronine (T3), which is the metabolically active hormone (Figure 21-7). Deiodination occurs both in the thyroid gland and at peripheral sites such as liver, kidney, and brain. Thyroxine may also be deiodinated at its inner ring to form reverse T3 (rT3), which is metabolically inactive. Regulation of the relative activity of the inner and outer ring deiodinases to vary the concentrations of T3 and rT3 is a major control point in the thyroid economy. Thyroxine release from the thyroid is stimulated by thyroid-stimulating hormone (TSH, thyrotropin), which in turn is released from the anterior pituitary under the influence of the hypothalamic modulator, thyrotropin-releasing hormone (TRH). Perhaps in conjunction with T4, T3 feeds back to inhibit TSH secretion.

The influence of thyroid hormones on growth occurs at many levels. Within the cell, they have profound effects on metabolic processes, including the induction of mitochondrial enzymes and an increase in Na+, K+-ATPase activity. Thyroid hormones influence the GH–IGF axis, as evidenced by the fact that hypothyroid rats have a diminished pituitary content of GH, low circulating GH levels, and depressed IGF levels.[246–249] T3 has been shown to stimulate transcription of the GH gene.[250] In contrast to animal models, hypothyroid children do not consistently demonstrate subnormal GH release.[111,251,252] Furthermore, the growth-retarding effects of hypothyroidism in rats are not reversed by GH treatment. In addition to a GH-mediated influence on IGF secretion, thyroid hormones augment IGF-I actions on cartilage growth,[252] and their absence is evident at the growth plate cartilage by altered morphology.[253] In addition, some thyroid hormone actions on growth plate chondrocytes appear to be IGF-mediated, as the mitogenic actions of T3 on cartilage growth can be blocked with an antibody to IGF-I. In contrast, the effects of

T3 on cartilage morphology and functional maturation do not appear to be IGF-mediated, direct ones.[254]

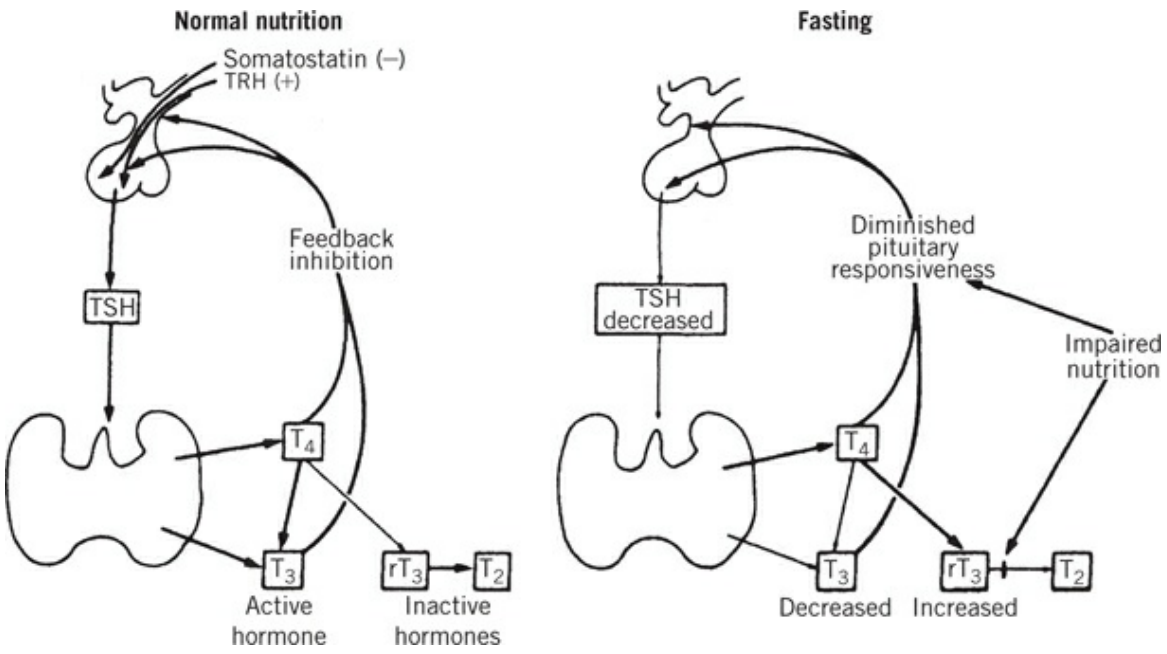

Figure 21-7 The pituitary–thyroid axis. A, When nutrition is normal, thyroxine (T4) is converted primarily to the calorigenic hormone triiodothyronine (T3) in the thyroid and peripheral tissues. Levels of the inactive hormones reverse T3 (rT3) and T2 are relatively low. B, After fasting, reverse T3 concentrations rise primarily because of decreased degradation to T2, and to some extent through preferential conversion of T4 to rT3. Fasting also diminishes the pituitary responsiveness to hypothalamic factors. Thyroid stimulating hormone (TSH) levels do not rise as in other forms of hypothyroidism. (+) stimulatory action; (−) inhibitory action.

Thyroid Hormones and Malnutrition

Fasting and malnutrition induce a hypothyroid-like state characterized by a diminished rate of T3 production and, consequently, a depressed heart rate and basal metabolic rate, as well as a diminished loss of nitrogen.[160,255,256] Similarly, bradycardia is a feature of anorexia nervosa. Concomitant with the fall in T3 in malnutrition is a depression of sympathetic nervous system activity, as measured by norepinephrine secretion.[257] Within 48 hours of a fast, T3 concentrations fall into the hypothyroid range while concentrations of T4 change little, and those of rT3, the inactive

metabolite of T4, rise (Figure 21-7). These changes result from a starvation-induced inhibition of the deiodination of T4 to T3, while the serum half-life of rT3 is prolonged by preventing its deiodination to T2. In addition, malnutrition also results in a diminished synthesis of the plasma thyroid-binding proteins, also leading to depressed thyroid hormone levels.

The low levels of thyroid hormones in the undernourished state are likely to be an adaptive mechanism meant to diminish the extent of catabolism. Silva have shown that when T3 is administered to fasting subjects sufficient to maintain T3 levels in the normal range, nitrogen losses are accentuated.[244] Despite a low serum T3, TSH secretion is not increased in fasting, and the TSH response to TRH is either normal or somewhat blunted.[256,258] The condition of depressed levels of metabolically active thyroid hormones without elevation in TSH in malnutrition or illness has often been called the "euthyroid sick syndrome" or "nonthyroidal illness syndrome," and recent developments in the field have cautiously supported the administration of thyroid hormones to individuals in this physiologic state.[259,260]

The depressed T3 levels of the fasted state can be corrected by refeeding as little as 100 kcal of carbohydrate, whereas the protein or fat content of the diet does not significantly affect the recovery of T3.[261] As little as 50 g of carbohydrate will prevent the effect of dietary restriction on serum T3 levels.[87] As in those subjected to acute starvation, chronically malnourished children and adults have depressed serum T3 and elevated rT3 concentrations. However, the TSH concentrations are either normal or elevated in chronic malnutrition, and the TSH response to TRH is exaggerated.[156,215,262]

CORTISOL AND SEX STEROIDS

Cortisol in Intestinal Maturation

Development of critical intestinal absorptive transporters and digestive enzymes is a prelude to somatic growth. There is a striking maturation of absorptive function of the intestine following birth, with ample evidence to suggest that glucocorticoids regulate the process. Most of the data on the regulation of gut maturation have been derived from studies in rats and other small mammals. Coincident with the period of weaning and, consequently, a decreasing reliance on lactose and other milk sugars for nourishment, there is a fall in the high activity of lactase in the small intestine and a rise in the activity of intestinal sucrase, maltase, and

pancreatic amylase.[263] In addition, there is a loss of the mechanisms by which the ileal and jejunal mucosa take up macromolecules and transport immunoglobulins. Delay of weaning has no significant effect on the timing of these changes. In contrast, deprivation of pituitary hormones by hypophysectomy in the newborn period elicits a marked delay.[264,265] These observations have led to studies of the role of pituitary-derived or pituitary-regulated hormones in the maturation of gut function.

The experimental data support roles for both glucocorticoids and thyroid hormones in intestinal maturation. Coincident with the enzymatic changes in the rat gut at the end of the second week of life, there is a prominent rise in circulating corticosterone. Breast milk might provide an additional source of glucocorticoids.[266] Glucocorticoid administration to preweanlings results in early maturation of intestinal enzymes such as sucrase[263] and of pancreatic amylase, bile acid synthesis, and transport phenomena such as bile salt absorption.[267] The dependence on glucocorticoids is not absolute; however, as adrenalectomy on day 9 of life does not prevent the appearance of sucrase or delay the maturation of sucrase to adult levels of activity.[263] A comparable role for thyroid hormones has also been suggested, although it appears that the ability of thyroxine to induce maturation of the intestinal enzymes requires the presence of intact adrenal glands. Administration of thyroxine to rats results in increased blood concentrations of corticosterone. Thus, the observed effects of thyroxine may be through induction of glucocorticoids.[263]

Cortisol in Malnutrition

Reflecting the metabolic stress, malnutrition in humans and laboratory animals results in elevated cortisol concentrations, with an abolition of the normal diurnal rhythm and a slowed clearance of exogenous cortisol.[268] Fasting also depresses production of cortisol-binding proteins, resulting in a further elevation of free glucocorticoids.[269] Despite the glucocorticoid excess, the adrenal glands remain suppressible with dexamethasone and responsive to ACTH in the malnourished state.

A prominent metabolic effect of cortisol is the diversion of substrates to the liver for protein synthesis. Rao and coworkers[270] have demonstrated that infants with marasmus have higher cortisol levels than do infants with kwashiorkor and that the response of cortisol to ACTH is better preserved in marasmus. Those authors postulated that the development of kwashiorkor is coincident with failure of the adrenal gland to secrete

adequate cortisol to maintain normal protein levels. In rats, the biochemical manifestations of kwashiorkor resulting from a low-protein diet can be reversed by glucocorticoids.[271] As previously indicated, glucocorticoids have a deleterious effect on cartilage growth and act as IGF antagonists in somatomedin bioassays. In his studies on malnourished Nigerian children, Smith[195] postulated that elevated cortisol, acting as an inhibitor of IGF action at the epiphyses was a major contributor to the poor growth of his subjects.

Reproductive Function in Malnutrition

The potent gonadal steroids testosterone and estradiol are primarily responsible for the establishment of reproductive fitness. Other, weaker androgenic hormones, however, which are produced by the gonads and adrenal glands of both sexes, are important in the maintenance of normal anabolism. These include androstenedione, dehydroepiandrosterone, and its metabolite dehydroepiandrosterone sulfate. Whereas reproductive functions are expendable and potentially damaging during times of nutrient deficit, considerable attention has been paid to the importance of weaker androgenic hormones, or anabolic steroids, as possible therapeutic agents for the recovery from catabolic states.

In malnourished adults, hypogonadism often develops, and the secretion of sex steroids by the gonads decreases. In malnourished children, the onset of puberty is delayed.[272] Men suffering from chronic protein-calorie malnutrition often experience gonadal failure. In adults, nutrients appear to influence reproduction at both the hypothalamic and gonadal levels. In a group of Indian men suffering from malnutrition, Smith and colleagues[273] found low-plasma testosterone and elevated gonadotropins, indicating impaired testicular function. During recovery, these men continued to have elevated levels of luteinizing hormone and a subnormal release of testosterone to chorionic gonadotropin (hCG). In contrast, Klibanski[274] found evidence for hypothalamic hypofunction when mildly obese men were fasted for 10 days.

In addition to the effects of malnutrition in delaying puberty, a number of studies on young athletes have suggested a connection between body composition and reproductive fitness. In young female athletes and dancers who train extensively before puberty, menarche can be delayed by several years.[275] In some instances, the delay in menarche can be related directly to the duration of training prior to menarche: five months for every year of training.[276] These observations led Frisch and McArthur[277] to

propose that normal menstrual function depends on the attainment of at least 22% body fat. This model assumed that some aspect of body fat content signals permission for the secretion of gonadotropic hormones to trigger menstruation. The identification of leptin as the adipocyte-derived product of the ob gene, has shed some light on the relationship between body fat and puberty. Leptin levels in the blood increase with adiposity. Leptin receptors have been identified in the anterior pituitary and gonads, and leptin accelerates the pulsatility of gonadotropin releasing hormone as well as being critical for the synthesis of adrenal androgens.[278]

Anabolic Steroids as Therapeutic Agents in Catabolic Disease

Despite all attempts, it has been impossible to synthesize steroids with anabolic actions that are divorced from their androgenic (masculinizing) ones. Coupled with their anabolic effects, these hormones also have behavioral effects such as increased aggressiveness and an enhanced appetite. Like all androgens, synthetic anabolic steroids suppress gonadotropin production and result in a lipogenic profile of cholesterol metabolism. High doses can alter liver function and result in hepatocellular carcinoma. Anabolic agents have been shown to decrease nitrogen loss after minor surgery,[279] but have had no consistent effect on weight gain in geriatric patients[280] or in patients with chronic renal failure.[281]

There has been considerable popular attention in recent years to the use of anabolic steroids to increase performance in bodybuilding and other sports. Well-controlled studies in adult male athletes are few, and the results are conflicting.[282] Those whose performance stands to benefit the most from increased androgenic activity are those who produce relatively low levels of androgens endogenously: females, prepubertal children, and adolescents. These are the groups in whom additional adverse effects such as virilization, balding, sexual precocity, and premature closure of the epiphyses would be the most damaging. At this time, there appears to be no clear role for anabolic agents in the treatment of catabolic states. Their use in augmenting athletic performance entails significant medical risk, including hyperlipidemia, glucose intolerance, liver dysfunction, thromboembolic events, and mood swings.

SUMMARY AND CONCLUSIONS

The humoral controls on growth are highly sensitive to the nutritional

milieu and are programmed to alter and even abort the body's developmental scheme as required during conditions of nutritional want or excess. The specific components of the diet that are monitored by the various nutritionally sensitive endocrine systems are still not known. However, our understanding is growing as to how nutrients can alter the expression of specific genes that encode key regulatory hormones, growth factors, and enzymes. A careful assessment of physical growth and maturation can serve as a sensitive and accurate index of nutritional status and disease, both for individuals and for whole populations.

The capacity of the growing organism to accommodate changes in the availability of nutrients by slowing or halting growth is a generally reversible process, designed to permit adaptation to a changing nutrient supply. However, the ability to resume normal growth after the correction of metabolic insults is dependent on the nature of the insult, its duration, and the developmental phase of the organism during which it occurs. The damage incurred during certain susceptible periods of growth may be irreversible, perhaps owing to a reduction in the number or critical organization of the cells that make up key tissues. The mechanisms by which a tissue or organism can monitor its own size and correct discrepancies with its "intended" size are unknown. They probably involve coordination between mechanisms for catch-up that are extant in individual tissues and regulatory centers in the CNS; classic hormones probably do not play a key regulatory role.

Recent years have brought the discovery of new hormone systems with close ties to the nutritional status of the organism. The discoveries of leptin, an appetite suppressant produced by adipose tissue, and ghrelin, an appetite stimulant produced in the alimentary tract, shed new light on how the body monitors its nutritional status. Other adipocyte-secreted substances such as Acrp30 and resistin may contribute to the insulin-resistant state of obesity. We have an abundance of candidate molecules to begin to elucidate the mechanisms involved in obesity and diabetes and to suggest therapeutic strategies against these disorders.

From our current vantage point, the metabolic changes of undernutrition are adaptive ones, designed to ensure survival until adequate reserves exist to permit growth and reproduction again. In some instances, however, morbidity may actually result from maladaptive endocrine changes. The development of kwashiorkor, for example, may result when the adrenal gland is no longer able to maintain adequate production of glucocorticoid hormones to facilitate withdrawal of proteins from structural stores, such as muscle.

A better understanding of the normal regulation of hormones and growth factors in conditions of altered nutrition has suggested new diagnostic and therapeutic approaches. Administration of GH to individuals in catabolic states may hasten their recovery. Studies of anabolic steroid hormones in catabolic states have generally not been promising.

The future challenge is to better delineate the full spectrum of humoral and neuroendocrine changes that accompany nutritional alterations and to define those components of "nutrition" that are the actual signals that can regulate the production and actions of hormones and growth factors. The accelerated rate at which "new" hormone systems have been discovered illustrates the fact that we have not yet identified all of the relevant humoral control systems, let alone understand them. The characterization of genes identified by the Human Genome Project and the advent of new technologies such as proteomic analysis may allow us to finally identify all of the critical components of the interface between nutrition and cellular control. At this time, the measurement of growth factors, their receptors, and their downstream signaling events within tissues is an invasive proposition and of little clinical practicality. When the physiology of these substances is better understood, however, the promise for therapeutic intervention will be great.

Gastrointestinal Development: Implications for Infant Feeding

22

Josef Neu, MD, Martha Douglas-Escobar, MD, and Sandra Fucile, OTR, PhD

The field of gastrointestinal (GI) development has been advancing at a rapid pace in the past 30 years.[1] The level of GI maturity of an individual infant is a major determinant of whether the infant will be able to meet nutritional needs by sole use of the GI tract or parenteral means will be necessary. The GI tract is not only an organ for digestion and absorption of nutrients; it also performs major endocrine, neural, and immunologic functions. In this chapter, anatomic, functional, and biochemical development will be described and related to means by which enteral nutrition can be used to optimize health and prevent disease (refer to Table 22-1 for a chapter overview).

ANATOMIC DEVELOPMENT

The intestine undergoes tremendous growth during fetal life. It elongates 1000-fold from 5 to 40 weeks gestation. The length doubles in the last 15 weeks of gestation reaching a mean length at birth of 275 cm. In the small intestine, fingerlike projections, villi, are already formed at 16 weeks gestation. In the large intestine, villi are also present, but these partially regress at around 29 weeks gestation. Microvilli begin to cover the apical surface of the small intestinal epithelium so that by adulthood, the intestinal surface provides the largest interface between the outside

environment and the internal milieu (approximately 200 m^2, which is about the size of a tennis court).

There are numerous cell types in the small intestine. These include the enterocytes (intestinal absorptive epithelium), Paneth cells (involved in secretion of defensins and other peptides implicated in the innate immunity), goblet cells (involved in the secretion of the mucous lining the intestine), and other cell types involved in the intestinal neuroendocrine and immune systems. After intestinal epithelial cells undergo mitotic division in the crypt, they migrate up the villus, where they undergo differentiation and become actively absorbing cells, then after apoptosis, become sloughed into the intestinal lumen. There is only one population of cells that migrate deeper into the crypt and these are the Paneth cells. Specific details regarding these cell types will be discussed later in this chapter.

TABLE 22-1 Developmental Challenges for very low-birth-weight (VLBW) Infant's Enteral Nutrition

Specific Developmental Challenges	
1. Mechanical development	a. Coordination of suck–swallow and breathing b. Low gastroesophageal sphincter tone c. Gastric emptying d. Intestinal motility
2. Absorption development	a. Proteins: only enteral protein are trophic for intestine b. Lipids: differences between medium- and long-chain fatty acids c. Carbohydrates: specially lactase enzyme
3. Innate defenses development	a. Gastrin b. Pancreatic secretions c. Secretion of defensins d. Specialized gut junctions e. Microbiota
4. Other challenges	a. Lack of initial enteral feedings b. Low volume of feeds c. Need for nutrients that decrease inflammatory state d. Need for nutrients for the colonocyte: short fatty acids

DEVELOPMENT OF MECHANICAL FUNCTION

Oral feeding is a major developmental milestone for the premature neonate and is one of the main criteria for hospital discharge. Oral feeding readiness is linked to GI tract functional aspects such as suck–swallow coordination, gastroesophageal sphincter tone, gastric emptying, and intestinal motility. These will be discussed separately albeit they function along as a continuum in the GI tract to propel food from the mouth to digestive absorptive areas.

Suck–Swallow Coordination

Suck and swallow are present as early as 17–18 weeks gestation. However, preterm infants born less than 32 weeks gestation have underdeveloped oral musculature, consequently they have difficulty latching on the nipple, difficulty initiating and sustaining a suck, and an immature and inefficient suck and swallow pattern compared to term infants.[2] In addition, they also present with difficulty coordinating suck-swallow-breathe processes due to their cardiorespiratory immaturity. Although respiration is always inhibited to accommodate swallow, preterm infants have a higher occurrence of swallows during inspiration and prolonged respiratory pauses.[2] These patterns put them at high risk for apnea, bradycardia, oxygen desaturations, and tracheal aspiration during oral feeding. Therefore, the current practice is to provide enteral feedings by tube (naso- or orogastric) until about 33–34 weeks gestation, when the coordination of suck-swallow-respiration begins to resemble that of full term infants. However, this practice remains subject to other immaturities such as, gastroesophageal reflux, poor gastric emptying, and dismotility. Also, feeding tubes may produce hypersensitivity and oral aversion because they are a constant nociceptive stimulus in the oral, pharyngeal, and esophageal areas. Provision of early (before oral feedings are started) sensorimotor therapies, and different infant positions and nipples are various interventions that can be used to prevent or reduce suck and swallow problems.

Gastroesophageal Sphincter Tone

Ganglia are present in the esophagus at five weeks gestation and complete their migration to the rectum by 24 weeks gestation. Despite this, the esophagus of the premature infant demonstrates slower propagation velocities and longer contraction duration than in the older child. At about 28 weeks gestation, the lower esophageal sphincter resting pressure is only

4 mmHg, but it increases to adult values (18 mm Hg) by term.[3] The prevalence of gastroesophageal reflux *disease* (GERD) is a debatable issue. At present, most of the techniques to determine GERD rely on acid measurement, but it is known nonacidic reflux cause reflex apnea. Modest changes in intra-abdominal pressure (such as changing a diaper) dramatically increases gastroesophageal reflux (GER) episodes.[4] Although GER episodes are frequently associated with apnea and bradycardia, there is no clear evidence of cause–effect relationship. Patients with persistent apnea-bradycardia and reflux even after changes in feeding techniques (e.g., changing bolus feeds to feeds over 1–2 hours) often receive empirical antireflux medication trial. Studies employing newer techniques of measuring reflux based on nonacid measurements (e.g., impedance) may yield important new information in this area. The recent suggestion that low-birth-weight infants with GER have an increased risk of esophageal adenocarcinoma in adulthood, makes this area a research priority.[5]

Gastric Emptying

Gastric emptying is slower in premature than in term infants[6,7] and leads to a greater residual volume of gastric contents—thus, it is closely tied to the problem of GER. Infants born between 32 and 39 weeks gestation decrease gastric emptying in response to progressive increments of caloric density.[8] Isocaloric formulas do not change gastric emptying even when the osmolality increases from 279 to 448 mOsm/kg.[8] During the last trimester, the fetus normally swallows up to 450 mL/d of low caloric density amniotic fluid.[9] Preterm infants have difficulty tolerating formula or breast milk with high caloric density. In adults, the rate of gastric emptying is controlled by feedback from the small and large intestine. Stimulation of duodenal receptors by acid, fat, carbohydrates, tryptophan, or increasing osmolality decreases rates of gastric emptying.[8] Very little information is available on the ability of duodenal feedback to control the rate of gastric emptying in infants born between 25 and 32 weeks gestation. One technique to improve feeding tolerance is the use formulas that promote fast gastric emptying (e.g., formulas with low carbohydrate or lipids). However, this technique may not be practical because extreme premature newborns have higher caloric demands to grow. Transpyloric feeding (through nasojejunal tube) is often employed to decrease the likelihood of reflux-related aspiration and apnea, but there is little evidence supporting it decreases premature infants mortality or morbidity.

Several studies suggest that medications used to increase gastric emptying rates in children and adults are also effective in premature infants. Erythromycin improves feeding tolerance without significant side effects in premature infants, although some randomized trial results were inconclusive.[10–12] Metoclopramide increases gastric emptying rate in preterm and term infants,[13] but its known side effects (such as extrapyramidal movement disorders or tardive dyskinesia) are difficult to monitor in this age group. Cisapride is another prokinetic agent, but it was removed from the US market because its association with cardiac arrhythmias.[14,15]

Intestinal Motility

The small bowel motility patterns are not completely developed in preterm infants born before 28 weeks gestation. Gastro-anal transit ranges from 8 to 96 hours in premature infants as compared with 4–12 hours in adults. Infants born between 27 and 30 weeks gestation have disorganized small bowel motility patterns that gradually progress to a more mature pattern and migrating myoelectric complexes are present at 33–34 weeks gestation.[16] Important motility mechanisms such as the motilin receptor and the cyclic release of the motilin are not present until 32 weeks gestation. It is intriguing that erythromycin, a motilin agonist, improved feeding tolerance in some premature infants.[11,12] Whether erythromycin might act through mechanisms not related to motilin remains speculative. Minimal enteral feedings increase GI motility (details will be discussed later in this chapter).

DEVELOPMENT OF DIGESTIVE ABSORPTIVE FUNCTION

Protein Digestion and Absorption

Our knowledge of digestive–absorptive processes has increased significantly in the past three decades. Hydrolysis of protein begins in the acid environment of the stomach and proceeds distally in the intestine through the action of various proteases. Gastric acid secretion is limited in very low-birth-weight (VLBW) infants. In the first 24–48 hours after birth, intragastric pH remains around 5.5–7 (whereas the normal gastric pH in children and adults is 2–3) and is relatively resistant to pentagastrin. Pentagastrin doubles from the first to fourth week of postnatal life in

preterm infants.[17] Gastric acid serves as a barrier to microorganisms, thus the use of H2 blockers to decrease acid production may lead to a higher load of bacteria in the more distal regions of the intestine.[18] Critically ill low-birth-weight infants treated with H2 blockers have a higher incidence of nosocomial sepsis and necrotizing enterocolitis (NEC).[19,20]

The pancreatic protease digestive cascade is catalyzed by food-stimulated secretion of enterokinase from the upper small intestinal epithelium. Enterokinase catalyzes the activation of trypsinogen to trypsin, which in turn activates several other inactive zymogens into proteases. Active luminal enterokinase is detectable at 24 weeks gestation, but its activity level is relatively low and reaches only 25% of adult activity at term.[21] Low enzymatic activity may limit protein digestion and may be responsible for transluminal passage of larger antigens and/or microorganisms without breakdown by luminal enzymes. After luminal digestion, small peptides and amino acids are absorbed and transported to the villus capillaries. The absorptive proteases are present and fully active before 24 weeks gestation and should not be limiting step in the protein absorption.[22] This fact suggests that hydrolyzed protein could be better tolerated in premature infants. Indeed, one study demonstrated that hydrolyzed protein formula led to faster establishment of full enteral feeding than a nonhydrolyzed protein formula.[23] However, the mentioned study did not have a human milk group. Human milk is much better tolerated than formula.[24] Many hydrolyzed protein formulas are not nutritionally formulated for premature infants.

Lipid Digestion and Absorption

Lipid makes up about 50% of the nonprotein energy content of human milk and formulas. However, both preterm and term newborns have a relative pancreatic insufficiency when compared to older children and adults, which may result in mal absorption of certain types of lipids. The digestion of lipid can be split into three phases.[25] The luminal phase of lipid digestion involves lipase de-esterification of triglycerides to 3-monoglyerides and free fatty acids and bile acid-mediated micellar solubilization. Several lipases participate in the fat digestion including lingual, gastric, pancreatic, and epithelial lipases as well as the human milk lipase. The lingual lipase is secreted by glands at the base of the tongue and is involved in gastric lipid hydrolysis. Other lipases are produced in the stomach or secreted from the pancreas. The human milk lipase (absent in cow’s milk and formulas) becomes active in the small intestine lumen

only in the presence of bile acids.[25] Bile acids synthesized in the liver are critical to efficient fat digestion and absorption. VLBW infants have a low concentration of bile acids in the duodenum due to low synthesis and ileal reabsorption of bile.[26,27] Therefore, VLBW have a lower luminal micellar solubilization with the end result of lower lipid absorption than term infants. Long-chain fatty acids required bile acids for solubilization, therefore their absorption is inefficient when compared to medium-chain fatty acids. Nevertheless, meta-analysis of studies comparing medium-chain triglycerides (MCT) to long-chain triglycerides feeding do not show clear weight gain advantage.[28]

Lipid absorption and assimilation phases include permeation of fatty acids and 2-monoglycerides from the lumen into the cell, intracellular reesterification, chylomicron formation, and transport into the circulation. After luminal digestion, fatty acids and monoglycerides approximate the absorptive surface and enter the intracellular milieu by processes that are not yet well understood. MCT that entered to the enterocyte do not need reesterification or chylomicron formation and are taken directly into the portal venous system. In contrast, intracellular long-chain fatty acids undergo reesterification and chylomicron formation before entering into the lymphatic system (Table 22-2).[29] Therefore, MCT predominant formula is recommended when there is obstruction of the lymphatic system (e.g., chylous ascites).

Linoleic or Linolenic fatty acids are considered essential fatty acids (i.e., must be ingested because the human body cannot produce them).[29] However, there is considerable debate about the capability of preterm infants to convert the dietary essential fatty acids (18-carbon linoleic and linolenic fatty acids) into longer chain fatty acids (with 20 or more carbons). Long-chain polyunsaturated fatty acids (LCPUFAs) formed using desaturase and elongase enzymatic pathways are critical in the formation of eicosanoids and structural components of the central nervous system.[30] Preformed LCPUFAs are abundant in human milk, but are not found in commercial intravenous lipid preparations or, until recently, most neonatal formulas. A meta-analysis and systematic review showed advantages of docosahexaenoic acid (an omega-3 LCPUFA) supplemented formulas over unsupplemented formulas in behavioral and electrophysiologic-based measurements of visual acuity in preterm and term infants.[31,32] Although research suggests that LCPUFA supplementation provides visual benefit in VLBW infants, improvement in cognitive neurodevelopment is currently being investigated.[30]

Most of the lipids from the formulas or intravenous lipids are derived from vegetable oil (rich in omega-6 but not omega-3 LCPUFAs). Therefore, the majority of essential fatty acids provided to neonates are derived from the omega-6 family (linoleic acid). Ingestion of products derived from omega-6 fatty acids (2-series prostaglandins) have a greater systemic inflammatory effect than those derived from omega-3 fatty acids (3-series prostaglandins).[33] Although there is a considerable amount of information in adults about the omega-3 fatty acids ameliorating inflammation (e.g., rheumatoid arthritis, coronary artery disease, and other conditions), there is a paucity of information for neonates, particularly preterm infants. In animal studies, using a rat model, omega-3 fatty acid supplementation has been found to decrease the occurrence of NEC.[34] Whether providing omega-3 lipids supplementation will decrease NEC, chronic lung disease, or neurologic problems related to inflammation in human infants warrants further investigation. New designs of lipid solutions are attempting to add MCT and fish oil to the traditional oleic acid solutions.

TABLE 22-2 Comparison of Short, Medium, and Long Chain Fatty Acid Digestion and Assimilation

Overview of Fatty Acid Uptake
Short- and medium-chain fatty acids
Enter portal blood directly from enterocytes
Bound to albumin in blood
Albumin–FFA complex
Oxidized in liver or elongated and used for triglyceride formation
Long-chain fatty acids
Form Chylomicrons in intestinal cell
Drain into the lymphatics via the lacteal
Enter bloodstream at the thoracic duct
Upstream from liver
Slow entry into the blood

Overall, premature infants receive very little, if any, preformed omega-3 LCPUFAs while on minimal enteral feeding and/or parenteral nutrition and this is likely to have detrimental consequences in both nervous tissue formation and inflammatory responses.

Carbohydrate Digestion and Absorption

Neonates ingest carbohydrates either as natural lactose (the primary carbohydrate in human and mammalian milks) or glucose polymers, sucrose, or hydrolyzed starches. Pancreatic amylase hydrolyzes starches by cleaving internal α-1-4 glucose bonds to maltose, maltotriose, limit dextrin, and glucose. Pancreatic secretion of amylase is limited during the first several months of life; therefore starch hydrolysis is a limiting factor and leaves undigested starch in the intestinal lumen. Glucose polymers (18–29 glucose units) can be hydrolyzed by salivary amylases, but this digestion is not enough to compensate for the diminished concentrations of pancreatic amylase.[35] Many term and preterm infant formulas include partially hydrolyzed starches (such as corn syrup solids or tapioca) to overcome problems related with carbohydrate hydrolysis. The more extensively the starch is hydrolyzed, the greater increase in formula osmolality (and risk of hyperosmolar diarrhea and/or intestinal inflammation). Maturation of carbohydrate absorption mechanism has a defined progression during human fetal development.[22,29,36,37] The intestinal epithelial absorptive enzymes, lactase, sucrase, maltase, isomaltase, and glucoamylase, are at mature levels in the term newborn.[21] Preterm infants have sucrase, maltase, and isomaltase almost fully active, but low lactase activity, depending upon gestational (lactase activity increases markedly from 24 to 40 weeks gestational age).[21] Despite this developmental lactase deficiency, clinical lactose intolerance is uncommon. Postnatal adaptive responses to ingested carbohydrates lead to competent carbohydrate utilization.[38] Furthermore, there is a colonic salvage of nonabsorbed carbohydrates. The colonic microbiota ferment the nonabsorbed carbohydrates to hydrogen gas and short-chain fatty acids (SCFAs), which are easily absorbed by the colonocyte.[36]

Feeding route and composition of the milk (or formula) affect the lactase activity in the small bowel.[38] Preterm infants receiving early enteral feedings (before 4 days of age) have greater lactase activity than control group (feedings initiated after 15 days of age) at 10 and 28 days of age by 100% and 60%, respectively. Lactase activity was greater in human milk- versus formula-fed infants at 10 days of age. Lactase activity was inversely related with the time required to achieve full enteral feedings and the total number of abdominal X-ray examinations per infant. These findings show that early enteral feeding increases lactase activity in preterm infants.

VLBW infants' feedings are seldom initiated at levels intended to meet

the infants' entire nutritional requirements and usually feeds are advanced slow, therefore they are unlikely to exceed the lactose hydrolysis capacity and intestinal salvage ability. The use of lactose-free formula instead of human milk or lactose containing formula is not appropriate to feed premature infants and theoretically can be harmful. High lactose concentrations in human milk should not be a contraindication for its use in the VLBW infants. This is especially unlikely when the quantity fed is less than 50% of the caloric requirement provided via the GI tract (unless the infant's bowel has been radically shortened by surgery). Human milk also contains several lactose-derived oligosaccharides and other glycoconjugates that may play an important immunologic role.

Studies examining the crypt to villus gradient of intestinal carbohydrase activities demonstrate that the majority of lactase activity is found at the mid-to-upper villus, whereas sucrase, maltase, and glucoamylase are concentrated at the mid-villus region.[39,40] This is likely to be pertinent to intestinal injury and villus damage. Lactase is usually the first enzyme to be lost and the last to be fully regenerated after injury. Congenital lactase deficiency is extremely rare. A large proportion of the world's population develops lactose intolerance in the first few years of life because of a decline in lactase activity, but further discussion is beyond the scope of this chapter.

INNATE DEFENSE AND BARRIER FUNCTION DEVELOPMENT

The GI tract presents the largest surface area of the body to which antigens and microbes are exposed. The intestine must therefore have intricate mechanisms to allow entry of nutrients and other beneficial molecules while preventing potentially harmful microbes and other agents from gaining entry into the inner milieu. Shortly after birth, the establishment of an intestinal bacterial community is very important for maintenance of normal homeostasis. Several factors lead to a hostile GI environment that predisposes the VLBW infant in the neonatal intensive care unit (NICU) to disease. These include the introduction of feeding tubes into the stomach or more distal intestine, the use of broad-spectrum antibiotics that select for the NICU-resistant pathogens, the restriction of enteral feedings, and the intrinsic functional problems of the preterm infant's GI tract. The combination of total parenteral nutrition (TPN), lack of enteral nutrition, and the introduction of a hostile microbiota into an immature GI tract offers a fertile environment for GI-derived systemic inflammation and

programming of pathologic immune responses.

Intestinal defenses may be broadly divided into innate and adaptive categories. The importance of the innate system is that it constitutes the first line of host defense. Each of the components of the innate system acts in concert to maintain mucosal integrity in the intestine. Several of these components are presented here.

Breast Milk

Breast milk is a protective component of innate defense for the neonate. Breast milk provides immunoglobulins, lactoferrin, lysozyme, glycoconjugates, oligosaccharides, and various types of white blood cells. Antibodies in human milk reflect the antigenic repertoire of the mother's intestine and respiratory tract. Colonization of the lactating mother's intestine with specific strains of *Escherichia coli* results in the appearance of corresponding antibodies in the mother's milk.[41] This effect is achieved by seeding primed plasma cells to the breast tissue. The array of antibacterial, antiviral, antifungal, and antifood antibodies in human milk is considerably vast. This repertoire varies from mother to mother and is modified by the antigens ingested and inhaled by the infant.[42] Mother and babies in close contact have similar bacterial colonization and the maternal breast milk has specific antibodies for the infant protection. This defense is referred to as "enteromammary immune system."[43] Furthermore, mother's milk contains commensal bacteria that may play a protective role and act as a natural "probiotic."[44] Oligosaccharides in mother's milk are "prebiotic" because they provide nutrients for beneficial commensal bacteria. In addition, the oligosaccharides are "postbiotic" because its fermentation produces SCFAs used as a main fuel by the colonocyte. Butyrate, one of the short fatty acids, is an antiapoptotic, pro-proliferative agent that is associated in the strengthening of intercellular tight junctions,[45] and stimulation of the synthesis of the glucagon-like peptide-2 (an intestine trophic hormone).[46] Human milk contains high levels of interleukin-10 (IL-10) and transforming growth factor-beta, anti-inflammatory cytokines that modulate intestinal inflammation.[47]

Gastric Acid and Pancreaticobiliary Secretions

Gastric acid and pancreaticobiliary secretions decrease the load of viable microorganisms and intact dietary protein antigens that reach the small intestine, as previously discussed.[48] The newborn relative pancreatic insufficiency can last through the first year of life.[49] Low gastric and

pancreaticobiliary secretions allow a greater bacterial and/or antigenic load to pass into the distal intestine. In normal conditions, GI tract proteolysis destroy the spatial structure of antigenic proteins, including the antigen epitopes for immunologic recognition.[50] Animal studies demonstrate that GI alkalization increases the passage of intact proteins such as bovine serum albumin in rats.[51] In addition, H2 blockers lead to greater bacterial translocation in newborn rats.[18] These findings are concerning because during the first few days of life, many VLBW infants have no or minimal stimulation of gastric acid and intestinal proteases (due to lack of enteral feeding during first days of life and H2 blocking agents therapy). Therefore, these infants have more intestinal exposure to intact protein molecules and bacteria, increasing the risk for allergies and infections. This could explain why VLBW infants receiving H2 blocking agents have high incidence of hospital-acquired sepsis and NEC.[20,52]

SURFACE EPITHELIUM

Intestinal Absorptive Epithelium

The absorptive lining epithelium of the primitive intestine is initially stratified but becomes a single layer of columnar cells at the end of the first trimester. The intestinal epithelial enterocyte derives from the same undifferentiated stem cell that gives rise to columnar absorptive epithelium, mucus producing goblet cells, Paneth and M cells in the intestine.[53] The function of these cells, beyond nutrient absorption, is well recognized, and some of their major roles include bacterial mucosal cross talk and innate barrier function.

Goblet cells. These are specialized mucus-secretory cells found throughout the intestine. Goblet cells mature from the base of the crypt (proliferative zone) and migrate along the crypt–villus axis. After 5–7 days, they reach the tip of the villi and are exfoliated (by a particular programmed cell death called “anoikis”). Goblet cells secrete mucus/mucin, which are very important in the nonspecific protection of the gut lining. Intestinal mucus is a complex gel that covers the surface of the villous epithelium and contributes significantly to cytoprotection at the same time that it offers many ecologic advantages for the microbiota. It is composed primarily of water and electrolytes but also contains mucins, glycoproteins, immunoglobulins, glycolipids, and albumin.[54] Bioactive factors such as lactoferrin, lysozyme, and glycolipids from breast milk may also be contained within the surface mucus gel.[55] Mucus is secreted

into the lumen of the intestine from storage vacuoles in goblet cells, and these cells are interspersed among enterocytes along the villus to crypt axis. Mucous gels are sufficiently stable to keep foreign dietary antigens and pathogenic bacteria trapped. In response to a threatening insult, the intestine can release rapid outpouring of mucin and resident microbiota can induce an increase in the production of mucins. Mucins may be classified according to their structure as gel forming, soluble, and membrane bound. Mucins develop binding sites for lectins, selectins, adhesion molecules, growth factors, cytokines, and chemokines, suggesting that they are implicated in cellular signaling. Mucins lower the diffusion of large molecules (which limit the antigenic load exposure), but allow the passage of small nutrient molecules. Mucins composition change during development. Mucin from small intestine of newborn rats contains more protein than does the adult rat intestine.[56] Carbohydrate composition also changes; the newborn has less fucose and *N* acetyl-cysteine than does the mucin from adults. Levels of mucin in the small intestine decrease in experimental protein-calorie under nutrition, which reduce the GI protection during the perinatal period.[57] Perinatal malnutrition lowers the amounts of mucin, diminishing infant's protection. Certain nutrients such as threonine have a major effect on mucin production[58] and need to be considered in the nutrition of critically ill infants.

Paneth Cells. Paneth cells represent one of the four major epithelial cell lineages in the small intestine and are the only lineage that migrates downward into the crypt base after originating in the crypt stem cell region. The location of Paneth cells adjacent to crypt stem cells house suggests that they play a critical role in defending epithelial cell renewal. In response to pathogen attack, the Paneth cells secrete a wide spectrum of *antimicrobial peptides* (AMPs) against gram-negative and gram-positive bacteria, fungi, protozoa, and viruses. The AMPs are able to kill the pathogens by different mechanisms. They are able to attach to and insert into microbial membrane bilayers to form pores, reduce the synthesis of cell wall and nucleic acid, and inhibit enzymatic activity. Some of the major enteric pathogens have developed resistances to AMPs as a way to evade innate mucosal defenses.

One of the main group of AMPs secreted by Paneth cells are alpha-defensins, also known as cryptdins.[59] These peptides have hydrophobic positively charged domains that can interact with phospholipids in the cell membranes. These domains allow formation of pores that disrupt bacterial membrane function, leading to bacterial death. Paneth cells are stimulated to secrete defensins when exposed to gram-positive or gram-negative

bacteria or other bacterial products such as lipopolysaccharide (LPS). Alteration of AMPs is detrimental to the neonate's small bowel defense against *E. coli* infection. In addition to defensins, Paneth cells secrete other antimicrobial enzymes such as lysozyme and phospholipase A2. These battery of peptides secreted by Paneth cells are an effective host protection against bacteria, fungi, and even some enveloped viruses.

M-cells. M-cells in the intestine do not have well-developed microvilli and allow macromolecular transport, whereas the absorptive enterocyte has better developed microvilli. M-cells are present only in the follicles that overlie organized mucosa- associated lymphoid tissues.[60] M-cells are specialized in presenting foreign antigens and microorganisms to organized lymphoid tissues within the mucosa of the small and large intestines. Thus, M-cells play a major role in specific immunity to luminal antigens. However, M-cells' role in neonatal diseases is unknown.

Specialized interepithelial junctions. Unique mechanisms are required to allow or prevent passage of substances between intestinal epithelial cells. Special junctions and interdigitations join the intestinal epithelial cells as seen in Figure 22-1. The tight junction (zonula occludens) is the most apical component of the junctional complex and serves as the permeability barrier between the external and internal milieus of the body. The tight junction completely encircles the apical end of absorptive cells as a belt-like band. Several transmembrane proteins on the cytosolic leaflet are part of the tight junction. These include the claudin and occludin protein families. Interactions of some of these proteins with the actin cytoskeleton are a major determinant of tight junction structure and play a role in the regulation of tight junction assembly.[61] Just below the tight junction, the adhesion junction (zonula adherens) is connected to actin filaments in the cytoplasm and anchors each cell to adjacent cells. Below this, the desmosome (macula adherens) functions in a similar manner to the zonula adherens. The relationship between density of zonula occluden strands and epithelial resistance has been demonstrated in cell culture studies.[62] These junctions allow for physiologic passage of fluids, electrolytes, and small macromolecules up to 11 amino acids long,[63] but larger proteins may not pass this route under physiologic conditions. However, pathologic insults may alter these junctions so that they allow abnormal passage of particles. In addition, these intercellular junctions are exquisitely sensitive to modulation by small molecules. SCFAs produced by bacterial fermentation such as butyrate has been shown to enhance restoration of mucosal barrier function after injury.[64] Administration of glutamine (GLN), an amino acid known to be conditionally essential

during critical illness, can also prevent the disruption of tight junctions and subsequent increased paracellular permeability induced by a variety of insults.[65,66] Our ability to manipulate these junctions may be key for prevention of several diseases that are autoimmune in nature and may at least partially relate to "a leaky gut" in its pathogenesis.[67] Figure 22-2 illustrates some of these diseases.

Epithelial turnover and restitution. It is unclear whether the infant can respond to injury to the same extent as the adult. In mammals, the intestinal epithelial turnover is much slower in the infant (4–5 days) than in the adult (two days).[68] If the turnover in human neonates is longer than the adult, as in other mammals, is of significance in that regeneration of injured mucosa in the infant will be much slower than the adult. In addition, environmental factors may contribute to poor restitution in intestinal epithelial cells after injury. In an animal model of NEC, it was determined that intestinal restitution was significantly impaired compared to control animals.[69] The mechanism of this effect was evaluated in vitro with rat crypt cells (IEC-6), which were shown to undergo significant inhibition of restitution after exposure to LPS.[69] GLN has been demonstrated to prevent cytokine-mediated apoptosis in human colonic cells.[70] Another amino acid, arginine, also induced intestinal epithelial migration, but through the mammalian target of rapamycin (mTOR) pathway.[71] The role of these amino acids in counteracting intestinal stresses and insults warrants further investigation.

THE INTESTINAL ECOSYSTEM AND MICROBIOTA

It is clear that there is a close interplay between the major cell types lining the intestine, nutrients, and the microbiota, which are all constituents of the intestinal ecosystem. GI infections and antibiotic treatment reduce the normal commensal bacteria in the ecosystem. Reduced commensal bacteria alter normal stimulation of the GI immune response as well as the amount of nutrients available. Similarly, the lack of enteral nutrients negatively affects the host and the microbiota.

We are beginning to appreciate the profound changes that occur in the intestinal ecosystem when young mammals are weaned from their mother's milk. One example is the changes in the angiogenins, potent AMPs released from the Paneth cells of the crypt.[72] Mice rose in a conventional environment have a marked increase in angiogenins at the time of weaning from mother's milk to an adult diet. This change occurs to a much lesser degree in germ-free mice.[73] Commensal bacteria *cross talk*

with the GI tract and therefore the production of angiogenins is critical for normal villus capillary development. For example, mice grown in a germ-free environment have a lag in development of the villus capillaries in the small intestine when compared with mice grown in an environment containing normal mixed flora or only one species of commensal bacterium (Bacteroides thetaiotaomicron).[74]

Most of premature neonates receive broad-spectrum antibiotics at some point in their intensive care hospitalization. The effect of broad-spectrum antibiotics on the resident intestinal microbiota is not known, but there is indirect evidence that may be detrimental. In rodents, when the intestinal tract is depleted of microbes, there is a reduction in the ability of the intestine to tolerate otherwise benign insults.[75,76] Furthermore, genes responsible for intestinal development are altered even after treatment with only one antibiotic.[77] Most recently, there has been an explosion of research on oral supplementation with commensal bacteria (probiotics) for the prevention of diseases, such as NEC.

DEVELOPMENT, INFLAMMATION, AND NUTRITION

The reliance on parenteral nutrition while providing few or no enteral nutrients may be highly detrimental because it promotes intestinal inflammation, atrophy, and sepsis as seen in Figure 22-3. The role of enteral nutrients in the prevention of the intestine-derived inflammatory response syndrome is becoming increasingly recognized.[78] Certain individual nutrients may play an important role in modulating these effects. For example, GLN depletion in LPS-treated Caco-2 (an adult transformed cell line) and, even more dramatically, in H4 (human fetal cells) results in marked upregulation of IL-8 production.[79] Similarly, in infant rats fed a commercial diet by gastrostomy and stimulated with LPS, GLN, decreases chemokine-induced neutrophil chemoattractant (the rodent counterpart of human IL-8) production in the intestine.[80] Several studies have suggested similar effects in vitro for probiotics, but studies in neonatal animals showing regulation of intestinal inflammation by probiotics have only recently been published.[81] Studies in human intestinal epithelial cell cultures have also shown that human milk suppresses IL-1 beta-induced IL-8 production.[82] Many of these nutritional agents appear to be acting through modulation of nuclear factor kappa B (NF-κB) signaling and transcriptional regulation, but precise mechanisms are yet to be

defined.

INTERVENTIONAL APPROACHES TO NEONATAL ENTERAL FEEDING

Total Parenteral Nutrition, Minimal Enteral Nutrition, and Trophic Feeding

TPN may cover the neonate caloric needs, nevertheless lack of enteral nutrition contributes to breakdown of the intestinal mucosa, bacterial translocation, and systemic inflammation (Figure 22-3).[78] These changes are even more pronounced if the neonate is a premature or VLBW infant. VLBW infants are frequently stressed due to prematurity problems such as respiratory insufficiency, thermoregulation, systemic infections, and others. Because of the high protein requirements in VLBW infants, they are commonly started on TPN to provide more protein intake.[83] Most

VLBW infants receive TPN during the first weeks after birth (during the acute illness), then they start enteral feeds—either human milk or formula. This practice has improved neonatal nutrition, however, it is still suboptimal because of the lack of early enteral nutrients to stimulate the GI ecosystem. During the first weeks of life, some VLBW infants receive "minimal enteral nutrition" (enteral feeds that are <20% of total nutritional requirements to grow for at least five days) (Figure 22-3). Despite often being termed "trophic enteral feeds" it is unlikely that minimal enteral nutrition provides significant GI trophic effect and enhances the barrier function.[84] TPN is associated with hospital-acquired sepsis,[85] probably due to the translocation of intestinal bacteria and intestinal inflammation.[86] In an animal study, enteral nutrition reversed intestinal bacterial translocation and inflammatory cascade triggered by TPN.[87] Neonates, especially VLWB, may benefit from early intravenous amino acid intake because it can decrease catabolism and increase protein synthesis and somatic growth. Early enteral nutrition is very important to maintain GI barrier function and optimal GI tract development as well as a prevention or modulation inflammatory diseases, NEC, hepatic inflammation, chronic lung disease, and progression of periventricular leukomalacia.[88–90] There is a great need for optimization of an enteral formulation that can be safely used in critically ill infants as an adjunct to minimal enteral nutrition shortly after birth that will decrease the need for parenteral nutrition.

How to nourish the VLBW infant during the first 2–3 weeks of life, when they are more critically ill and in catabolic state is one of the main challenges in neonatology. This is a period of extreme vulnerability and high nutrient requirement. A deficiency of essential nutrients during this time may result in significant short-term morbidity as well as lifelong consequences. Hence, "When and how quickly should we start and advance enteral feedings in preterm infants?" is a prominent clinical question. Because of individual characteristics of each infant, one feeding protocol or guideline is not appropriate for all infants. From the available studies, minimal enteral feedings should be instituted within the first days of life. There is no evidence that minimal enteral nutrition increases the risk of NEC in infants with mechanical ventilation, continuous positive airway pressure, indomethacin therapy apnea and bradycardia episodes, or umbilical catheters. Infants on early minimal enteral nutrition have faster maturation of GI motor patterns and release of GI hormones than those without enteral feedings. In addition, infants treated with early minimal enteral nutrition reach full enteral feeds faster and have fewer feeding intolerance, without an increase in the incidence of NEC. Other important

consideration is the quantity and quality of the early enteral nutrition.[91] The volume of feeds does not appear to have a benefit in maturing motor function. Motor responses are similar if feedings are intragastric or transpyloric. Motor responses are unchanged with the formula temperature (chilled, room temperature, or warmed to body temperature). Speed of volume infusion affects the gastric emptying. Infants fed at slow infusion rates (over 120 minutes) display intense feeding response accompanied by brisk gastric emptying. However, when the same feeding volume is given over 15 minutes, this produces a duodenal motor response that is less intense and is associated with delayed gastric emptying. Diluted formulas produce less intense motor responses. Because two-thirds of preterm infants have immature duodenal fed pattern and delayed gastric emptying, many of them are not physiologically prepared to process bolus feedings as well as slow infusion feedings. Taken together, Figure 22-4 shows a strategy for starting early minimal enteral feedings in VLBW infants. However, multicenter randomized studies should test whether this approach is safe and efficient in VLBW infants.

FUTURE DIRECTIONS

The fetus receives about 450 mL/d of amniotic fluid through the GI tract during the last trimester of pregnancy,[9] whereas GI tract of premature infants during the first weeks of life receive only 5%–10% of the volume that would go through the intestine per day in utero. Thus, the GI tract of premature infants might be able to tolerate more volume than what is commonly provided. Osmolality and lipid composition of the feeds are critical factors for tolerance to enteral feeding, because they modulate gastric emptying and intestinal motility. There are several individual nutrients that could potentially enhance intestinal growth and function. Here, we will discuss a few of them; enteral protein, GLN, long-chain omega 3 polyunsaturated fatty acids, and SCFAs (Figure 22-5).

Protein

Protein is the major macronutrient required for growth, but parenteral amino acids do not provide trophic stimulation for intestinal growth. In animal models, trophic effect on the GI mucosa occurs when at least 40% of the caloric intake required for normal growth is supplied by enteral route.[84,92] This trophic effect is most likely derived from enteral protein rather than lipid or carbohydrates. Prevention of epithelial atrophy and mucosal growth is critical for the neonate to have normal GI tract

functions (such as digestion, absorption, barrier function) and to keep microbiota (that could protect from infections and modulate the inflammatory cascade).

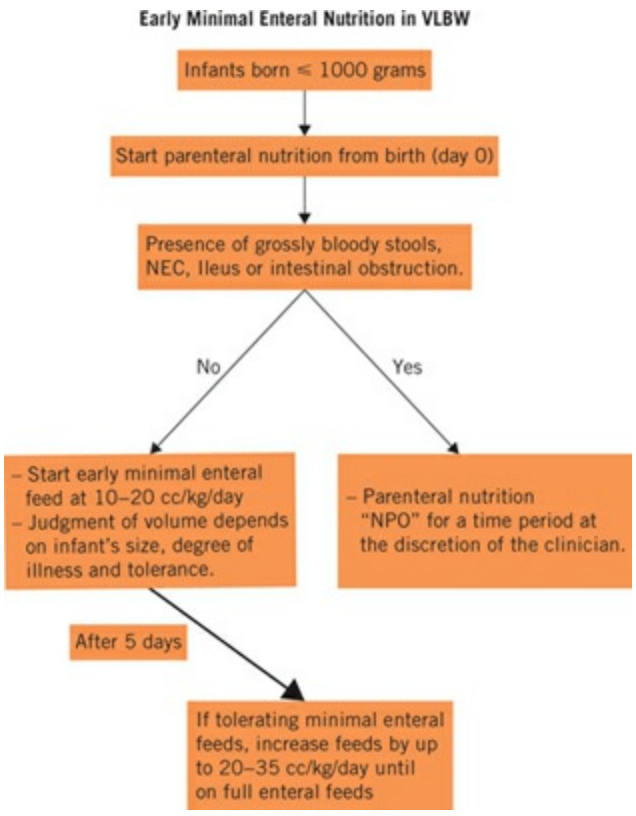

Figure 22-4 Early minimal enteral feedings in very low-birth-weight (VLBW) infants

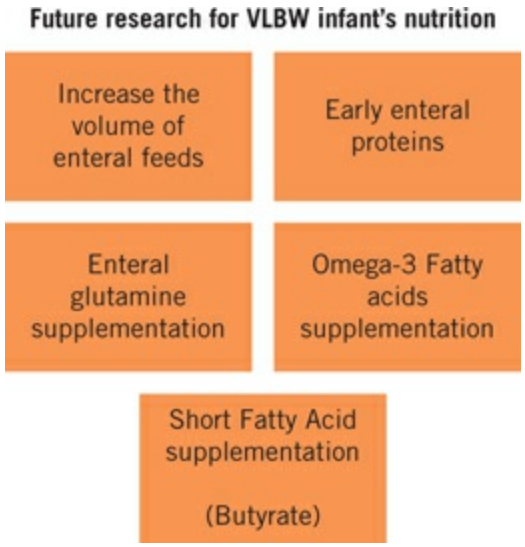

Figure 22-5 Future direction in very low-birth-weight (VLBW) infant's nutritional manipulation.

GLN

Most critically ill premature infants are not supplemented with the amount of GLN they would be receiving had they remained in utero. Lack of intestinal mucosal integrity and exquisite susceptibility to intestinal injury in VLBW infants could be associated to delayed enteral feeding and GLN deprivation. Several studies have demonstrated the efficacy and safety of GLN supplementation in highly stressed critically ill infants.[93–95] However, infants born prematurely receive very little, if any, GLN during the first weeks of life, because they rarely reach full enteral feedings (which contain GLN) for weeks and GLN is absent in routinely used TPN. VLBW infants with enteral GLN supplementation have less hospital-acquired sepsis, along with less CD16 and HLA DR markers on peripheral blood lymphocyte populations, consistent with decreased inflammatory response (probably secondary to decreased translocation of proinflammatory antigens).[93,95] In a recent multicenter trial, 649 VLBW infants with enteral GLN supplementation improved intestinal function and had less grades 3–4 intraventricular hemorrhages and periventricular leukomalacia.[94] However, one large study of intravenous GLN supplementation in neonates did not show any benefit in extremely low-birth-weight infants.[96] Studies on GLN supplementation should target infant subgroups (e.g., infants born to mothers with chorioamnionitis or

other inflammatory conditions), as well as compare dosage response, route, and timing of administration to fully understand and determine the beneficial effects of GLN.[97]

Omega-3 Fatty Acids

An important change to the composition of infant formula in the past several years has been the addition of LCPUFAs. The LCPUFAs added are docosahexaenoic acid (DHA, 22:6*n*–3) and arachidonic acid (AA, 20:4*n*–6). DHA and AA are integral structural components of all cells. Human milk contains DHA and AA. Infants fed with unsupplemented formulas have lower DHA and AA concentrations in their plasma and erythrocytes than do infants who are breastfed or fed supplemented formulas. Critically ill VLBW infants receive only minimal quantities of DHA and AA during the critical illness, through minimal enteral nutrition or TPN. Intravenous lipids are composed of the pro-inflammatory omega-6 fatty acids. Omega-3 LCPUFAs from fish oils and seed extracts decrease the production of inflammatory eicosanoids and cytokines. They inhibit AA metabolism and alter the expression of inflammatory genes through effects on transcription factor activation.[98] Thus, omega-3 LCPUFAs are potential anti-inflammatory agents. Future randomized multicenter studies should determine whether omega-3 LCPUFAs could improve clinical outcomes in VLBW infants.

SCFAs

SCFAs, especially butyrate, play central metabolic roles in maintaining the mucosal barrier in the gut. These SCFAs are a product of bacterial metabolism of carbohydrates, and responsible for several beneficial effects of commensal bacteria or probiotics.[45] Therefore, SCFAs are considered "postbiotics." The use of probiotics for premature infants is very controversial due to safety concerns in providing live bacteria to immunocompromised hosts. Butyrate offers some of the benefits of probiotic bacteria without side effects. Butyrate increases wound healing and reduces inflammation in the small intestine. Butyrate is the main energy source for colonic epithelial cells and affects cellular proliferation and differentiation.[45] Luminal provision of butyrate improves wound healing after intestinal surgery and ameliorates symptoms of inflammatory bowel disease. Furthermore, butyrate stimulates intestinal L-cell to produce glucagon-like peptide-2 (a highly trophic peptide for intestine).[46,99] There is a paucity of information on the effects of butyrate

as a nutrient for the developing intestine.[45]

SUMMARY

We reviewed several aspects of anatomic, physiologic, and biochemical development of the GI tract. We explained the importance of the GI tract beyond the classic paradigm of digestion and absorption of nutrients for optimization of growth. Nutritional needs of premature infants are often difficult to meet due to GI tract functional problems such as coordination of suck and swallow, frequent GER, slow gastric emptying, and slow intestinal motility. We presented the importance of the GI tract for the neonatal immune system as well as for the GI colonization and development of the microbiota. Feeding practices (such as route, volume, quantity, and quality of enteral feeds) can alter the intestinal ecosystem and can have implications for health *beyond the neonatal period*. Enteral feeds are crucial for the normal development of the GI tract; thus we propose to start enteral feeds very early in premature infants. We also summarized some of the new horizon on nutritional manipulation for feeding problems in preterm infants.

Diet, Environment, and Gut Microbiota in the Metagenomic Era

Carlotta De Filippo, BSc, PhD and Paolo Lionetti, MD, PhD

INTRODUCTION

The human gut microbiota is a complex consortium of trillions of microorganisms, whose collective genomes or “metagenome” contains at least 100 times as many genes as our own eukaryote genome.[1] This essential “organ,” the microbiome, provides the host with enhanced metabolic capabilities, energy, nutrients, and bioactive compounds and provides an effective barrier or resistance to invading pathogens, resulting in education of the immune system and modulation of gastrointestinal (GI) development. Furthermore, this microbial community is also involved in detoxification of harmful exogenous and endogenous compounds. The role of the resident microbiota in the human gut and its profound effects on host health and daily well-being is now recognized as crucial. The composition of the intestinal microbiota plays a critical role in mammalian metabolism and, likely, in human health. Twins and mother–daughter pairs have more similar microbiota compositions than unrelated individuals,

suggesting that there could be a genetic influence over the microbiota.[2] However, monozygotic and dizygotic adult twins have equally similar microbiota, suggesting environment rather than genetics may drive familial similarities.[2] The extent at which factors such as environment and diet shape the human gut microbiota is still unclear, partly because these factors are often confounded. However, in terms of microbiota function, metabolic output and interactions with the host, diet, and other exogenous factors like antibiotics or xenobiotic compounds also play a dominant role.

NEW TECHNOLOGIES TO DESCRIBE HUMAN MICROBIOTA—THE METAGENOMICS APPROACH

In the twentieth century, our knowledge of the human microbiota was constrained by the ability to describe and study the biological functions of less than 100 cultivable bacteria. The species we described until year 2000 were also the most abundant ones, and given the special attention of funding agencies toward pathogens, we fundamentally ignored the genome to functions relation for the majority of our commensal, except in the case of a handful of bacterial species used in food production (lactobacilli) and shown to dominate the gut microbiota of breast-fed infants (bifidobacteria).

In the beginning of this century, a limited number of studies on cloning and sequencing libraries of 16S rRNA started opening a window with a view on the astonishing diversity of human microbiota. Despite their importance, these initial, noncultivation-based, diversity studies were limited by the costs and complexity of Sanger sequencing methods. In the past 10 years, the picture of our gut microbiota has rapidly passed from black and white to a surprising explosion of bright colors, thanks to the advent of next-generation sequencing (NGS) technologies.

METAGENOMICS AND THE NEXT-GENERATION SEQUENCING ERA

Metagenomics is the application of modern genomic techniques to the study of communities of microbial organisms directly in their natural environments, bypassing the need for isolation and lab cultivation of individual species, given that less than 1% of the microbes present in nature are cultivable. The studies in the case of human microbiota (the

bacterial community of a body district) can consist of DNA and also transcriptome, proteome, and metabolome analysis to assess the type of organisms and the genes present in the community: the so-called metagenome or microbiome.[3]

The molecular study of both the taxonomic and the functional gene composition of environmental microbial communities is now highly improved by the use of NGS,[4] mainly using Roche/454 and Illumina. Advances in DNA sequencing have dramatically reduced costs and markedly increased capacity, thus allowing culture-independent metagenomic methods to be readily deployed to characterize microbial communities (microbiota) associated with human body habitats at various stages of the human life cycle and in various populations.[5] The 16S rRNA gene is widely considered the major molecular marker in the taxonomic classification of bacteria and is considered a good phylogenetic chronometer. The 16S rRNA gene is universal in bacteria, contains regions that vary in genetic mutation rate, and is long enough to provide meaningful taxonomic data.[6] The 16S rRNA bacterial gene contains nine hypervariable regions V1–V9 (Figure 23-1).[7] The V1, V2, V3, V5, and V6 regions result in having a greater discriminating power in identifying bacterial genus and species in animal commensal microbial communities.[8,9]

The 454 Genome Sequencer FLX Titanium series (Roche) platforms is particularly suited for 16S rRNA-based surveys. This platform can produce in a single run about one million “reads” of high quality with an average size of 400 bp that is now increased to 700 bp, thanks to the last platform upgrade. Basically, using these platform researchers, we will be able to sequence the entire 16S rRNA gene without cloning and without problems in assembling incomplete partial sequences from short reads.

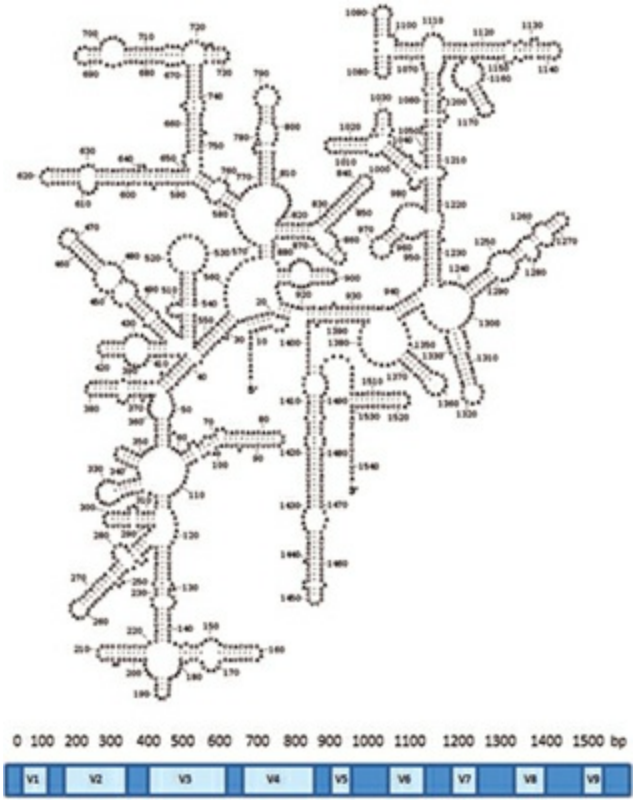

Figure 23-1 RNA secondary structure *Escherichia coli* 16S rRNA. 16S rRNA is a component of the 30S small subunit of prokaryotic ribosomes. It is 1.542 kb (or 1542 nucleotides) in length. The genes coding for it are referred to as 16S rDNA and are used in reconstructing phylogenies, in fact among the well-conserved structures of 16S rRNA (blue boxes), there exist nine hypervariable regions (V1–V9) that vary in their secondary structure from taxon to taxon. New DNA-sequencing technologies (NGS), such as massively parallel pyrosequencing, can provide orders of magnitude more DNA sequences than ever before to identify microbial taxa by comparing short tags from 16S hypervariable regions against a large database of known 16S genes. Using this technique, hypervariable region tags provide equivalent taxonomy and relative abundances of microbial communities as full-length rRNA sequences.

A significant further step has been made possible by approaches enabling the sequencing of every bacterial genome in the gut directly without isolation or cultivation in the laboratory, like Illumina-based NGS techniques. Illumina HiSeq2000 technology is based on a proven chemical technology useful for the sequencing of whole bacterial genomes.[10,11]

High-throughput sequencing technologies now allow for the first time access to the entire genetic repertoire or metagenome of a given environment without prior isolation or knowledge of microbial species make up. In metagenomic approaches, the analysis of the large amount of information contained in sequences generated by microbial sequencing “high throughput” from a complex environmental sample is now a major challenge. Importantly Illumina produces short reads at a significantly reduced cost. The real challenge of this technology is the heavy reliance on hardcore bioinformatics and computation required to assemble short reads from mixed samples by blasting the reads to databases of known sequences. The sequencing and subsequent bioinformatics analysis of DNA belonging to a microbial community is a great way to get information about its content and potential functional genes.[10,11] These new metagenomics surveys not only capture the microbial organism and genetic diversity associated with humans but also make it possible to investigate gene functions.[12] The combination of 16S rRNA and whole metagenome-based approaches holds the key to understanding the functional contributions that our microbes make to our physiologic phenotypes, our health, and our disease predisposition. However, the ability to reconstruct gut active metabolic pathways requires the combination of information on genes and protein sequences with the knowledge of metabolic patterns, which can be inferred from the measurement of the levels of associated metabolites in biological fluids (i.e., feces, urine, and blood).

METABOLOMICS

Direct sequencing metagenomic approaches allow us to access the genetic potential of a microbial community but does not provide in depth, real-time insight into the metabolic flux or kinetic of a microbial community at a given point in time. The human metabolome is the complete set of metabolites, end products of cellular processes, present in human biofluids at a given time. Metabolite profiling approaches represent the key to understanding the functional contribution of the gut microbiota to the host organism and its co-evolution with diet. Metabolomics, defined as a systematic study of the unique chemical fingerprints that specific cellular processes leave behind, allows us to characterize the metabolite profiles within a human biological sample such as stool, blood, urine, and breath, by using high-resolution analytical chemistry methods such as gas chromatography–mass spectrometry (GC-MS) or nuclear magnetic

resonance (NMR). GC-MS analysis represents a robust method for quantification of selected metabolites, with more satisfactory sensitivity and resolution than the conventional NMR approach.[13,14] This analysis is applied in metabolomics research of urinary and serum samples, brain tissue extracts, and fecal samples and allows the analysis of a certain class of metabolites such as fatty acids, phenolic acids, and amino acids in fecal water. The variation in metabolic profiles could depend on host genotype and disease status and also food intake (fruit, vegetables, dietary proteins, and fats) and on the composition of intestinal microbiota. Dietary carbohydrates, specifically resistant starches, and dietary fiber contained in fruits, vegetables, and whole grain cereals are readily fermented by the colonic microbiota to short-chain fatty acids (SCFAs), primarily acetate, propionate, and butyrate. These metabolites and their biologically active compounds modulate human nutrition and health, by decreasing the risk of developing GI and autoimmune disorders, allergy, and inflammatory bowel disease (IBD) through enhanced mucosal integrity and regulation of immune homeostasis, and also through protection from metabolic or obesity-related diseases.[15] SCFAs have been shown to impact on a number of physiological processes related to human energy metabolism including satiety and food intake (via induction of incretins), reducing low-grade systemic inflammation related to type 2 diabetes and nonalcoholic fat liver disease, and regulating lipogenesis and cholesterol metabolism in the liver.[16] Another important set of metabolites are amino acids and the by-products of their metabolism. The proportion of dietary amino acids that are metabolically available in the human body is influenced by digestibility, absorption, and genes of the gut microbiota involved in metabolism of amino acids. The availability of amino acid is important in humans for protein synthesis, modulation of gene expression, and intestinal integrity. Amino acid composition of foods varies greatly. In cereals and legumes, lysine and methionine concentrations, respectively, are significantly lower compared to foods rich in animal protein.[13] Amino acid availability in the colon is dependent on both endogenous sources (sloughed off epithelial cells and host digestive enzymes) and host diet. Food processing, especially heating, can affect the digestibility of proteins, impacting on the amount of protein reaching the colon as can the quantity of protein ingested. The Maillard reaction that occurs when food containing a mixture of carbohydrate/sugars and protein (i.e., most complex foods) is heated leads to the generation of advanced glycation end products, some of which are resistant to digestion by human proteases and reach the colon intact where they become available to the resident gut

microbiota. In terms of gross metabolic activity, there is a functional gradient within the colon. Carbohydrate fermentation is a more energetically favorable process for microorganisms, and available carbohydrates entering the colon are fermented preferentially, compared with other energy sources including protein. As this carbohydrate is used up, however, especially in modern affluent diets with low dietary fiber, microorganisms look for alternative sources of energy and switch to a proteolytic fermentation. Proteolytic fermentation by the gut microbiota, in addition to generating SCFAs and branched-chain fatty acids, results in the production of a range of harmful compounds that can be variably cytotoxic, genotoxic, or carcinogenic.[17] Thus, one important protective mechanism of diets rich in dietary fiber may be to prolong saccharolytic fermentation in the colon and reduce the harmful activities of amino acid fermentation.[18] By uniting metagenomics data with analyses of the products of microbial community metabolism (metabolomics), it is possible to shed light on how microbial communities function in a diverse human population with different dietary habits.[19]

THE CORE MICROBIOME

The reconstruction of the evolution of our dietary habits is crucial for understanding the evolutionary context of our modern diet and diet-associated diseases. The gut microbiota recovers energy and biologically active molecules, such as indigestible plant polysaccharides, from foods that would otherwise remain undigested and excreted by the intestinal tract, thanks to its microbiome enriched with genes for the breakdown of complex sugars. Resident bacteria are also involved in the biosynthesis of essential vitamins, isoprenoids, polyphenols, amino acids and the xenobiotic metabolism.

Turnbaugh et al.[2] performed a microbiota analysis on adult monozygotic and dizygotic female twin pairs and their mothers, similar for their physiological lean or obese state, trying to understand how the genome, environment, and fatness phenotype affect the microbial composition of the gut. The microbiome appears to be shared among relatives, while the composition of microbiota (mainly constituted by Bacteroidetes, Firmicutes, and in a lesser extent Actinobacteria and Proteobacteria) was found to be variable. Among all 154 individuals, 93%–98% of the genes belonged to a core functional group of genes shared among the microbiome.[2] Therefore, such findings suggest that humans may share a functional core microbiome instead of a core

microbiota. Deviations from this core turned out to be associated with different physiological states such as obesity, as well as reduced bacterial diversity and changes in bacterial genes and metabolic pathways present. The short-term temporal variations in the microbial community composition of an individual were found to be less marked than interpersonal differences. Close symbiotic integration of functions from the intestinal cells with bacterial cells suggests that human beings should be considered as “superorganisms” whose metabolism involves integration of metabolic processes encoded by the host genome with those encoded by the microbiome.[20] Initial work showed that the human microbiome composition varies among healthy people[1,20,21] and also between lean and obese individuals, and that it is responsive to dietary modulation for weight reduction.[22] Eckburg et al.[21] showed that the gut microbiota is highly diverse between individuals and comprises about 60% novel bacterial phylotypes and ~80% uncultivated species. This study supports the theory that gut bacteria evolution is a classic case of adaptive radiation, where a few successful colonizers gave rise to a variety of descendants, through diversification of an initial population bottleneck into various strains that likely correspond to ecotypes.

HOW DIET AND ENVIRONMENT COULD SHAPE OUR GUT MICROBIOTA

Despite the increasing number of metagenomic studies published, the complex interaction between diet and gut microbiota in human populations is still wide open to new discoveries. It is well known that human gut microbiota recover energy and biologically active molecules from food that would otherwise be discharged from the intestinal tract. Certain foods or food compounds interact directly with the gut microbiota, specifically those compounds which escape digestion in the stomach and upper gut and reach the colon, which is the home to majority of gut microorganisms. These compounds include nondigestible polysaccharides (prebiotics and oligosaccharides not targeted by human digestive enzymes or polysaccharides resistant to digestion due to chemical structure or physical inaccessibility) and plant polyphenolic secondary metabolites, 90% of which reach the colon.[19,23] These compounds are major components of whole plant foods, fruit, vegetables, and whole grain cereals. The fact that these compounds shape the activities of the gut microbiota is not that surprising when you consider how the gut microbiota must have evolved

alongside its human host. For humans from the earliest times, and our closest primate progenitors, plant-based foods formed the dietary mainstay. For nearly a million years, humans existed as hunter–gatherers, collecting wild fruits, vegetables, grasses, and tubers and supplementing their diet with wild animals and insects when available. Major changes in our diet occurred with the birth of agriculture,[24] reducing the diversity of species consumed, and with the agricultural and industrial revolutions (increasing access to processed and refined foods). However, it has been the last 50 years that has witnessed the most dramatic shift in human diet since we first diverged from our ancestral hunter–gatherer diets. After the Second World War and subsequent "Green Revolution" of the 1960s, intensive farming, dietary patterns in the "developed world" changed dramatically with increased access to processed energy-dense foods with high intake of saturated fat, red and processed meats, salt, sugar, and refined carbohydrates; low consumption of fresh fruit, whole-grain cereals, and vegetables; and consequently, low intake of dietary fiber and plant polyphenolic compounds. This dietary shift toward the "Western style" or modern affluent diet has long been linked to an increased incidence of chronic diet–associated diseases including obesity, type 2 diabetes, nonalcoholic fatty liver disease, cardiovascular disease, and certain cancers.[25,26] More recently, a dietary link to the concomitant increase in autoimmune diseases has also been suggested, but mechanisms remain elusive.[27,28] Similarly, high dietary intake of whole plant foods is considered protective against these same chronic human diseases.[29,30] One obvious implication of this dietary shift is that the type and quantity of food macromolecules reaching the colonic microbiota has changed compared to more traditional diets (e.g., traditional Mediterranean, African, and Japanese) and hunter–gatherer diets with probable implications for microbiota-related functions such as fiber fermentation and release of biologically active derivatives of phytochemicals. This identifies the human gut microbiota and their interactions with diet, as a focal point about which human health swings, with the potential to protect against chronic diseases of modern lifestyles and on the contrary as a contributory factor of autoimmune disease, metabolic diseases, and cancer.[31]

Until very recently, we lacked the tools to study in detail the consequences of modern affluent dietary composition on the makeup and activities of the human gut microbiota. However, the emergence of culture-independent microbiological techniques and most recently the application of postgenomics high-resolution genetic or metabolite profiling

approaches to study the gut microbiota have provided unprecedented insight into the microbial ecology of the human gut microbiota. A new subject area is emerging, which combines host genomics, immunology, metagenomics, metabolomics, food science (food chemistry, genomics, and biotechnology), and nutrition to service the observable interrelatedness of the foods we eat, our resident microbiota, and the human system in all its genetic, immunological, and metabolic diversity. Although usually used to define the interrelationship between plants and their mycorrhizal fungal partners, nutritional symbiosis defines well the relationship among foods ingested, the intestinal microbiota, and the human body.

Recent metagenomic studies have also highlighted important and previously unimagined means by which foods can modulate the composition and functioning of the gut microbiota and its composition species.

Gene transfer between bacteria in the gut has recently been shown to be influenced by the interactions between food and the gut microbiota. Among the Japanese, whose diet includes regular consumption of sushi, Hehemann et al.,[32] working with *Zobellia galactanivorans*, a member of the marine Bacteroidetes, discovered an enzyme (porphyranase) responsible for breaking down porphyran, an abundant polysaccharide in the red algae species *Porphyra*, on which *Z. galactanivorans* is often found. While searching gene-sequence databases, investigators came across predicted porphyranase sequences in metagenomes derived from human feces and in the genome of the resident human gut bacterium *Bacteroides plebeius*, suggesting that *B. plebeius* acquired the genes laterally from marine bacteria. After it turned out that these sequences were present in Japanese individuals but not in residents of the United States, the authors concluded that *Z. galactanivorans* were introduced through *Porphyra* (“nori”), the traditional seaweed used to wrap sushi and a common component of the Japanese diet. The researchers hypothesize that by regularly consuming seaweeds, Japanese communities produced a selective force that led to retaining the beneficial porphyranase genes in their gut microbiomes.[32] Earlier studies with animal models with a “humanized” gut microbiota showed that high-fat, Western-style diet can increase the rate of conjugative transfer of plasmids between bacteria within the GI tract.[33]

Such interplay between food and gut microbiota underlines the importance of food microbial composition in terms of both quality (e.g., presence of probiotic species) and safety (e.g., ratio of probiotics and pathogens) and implicates diet in the co-evolution of the human gut

microbiota in health and disease.

Another prominent role of gut microbiota is energy extraction from fiber and complex carbohydrates. Plant materials that are in fact indigestible by humans are a complex carbohydrate known as dietary fiber. Our bodies need roughage to properly digest food and eliminate waste because the bulky substance cleans the colon as it makes its way through our digestive tract. Dietary fiber comes from vegetables, fruit, grain, and legumes. The plant polysaccharides are rich in xylan-, pectin-, and arabinose- containing carbohydrate structures. The human genome lacks most of the enzymes required for degrading these glycans (see http://www.cazy.org/). However, the distal gut microbiome provides this capacity. At least 81 different glycoside hydrolase families are represented in the microbiome, many of which are not present in the human "glycobiome."[34] Host GI mucus provides a consistent reservoir of glycans for the microbiota and thus, in principle, can serve to mitigate the effects of marked changes in the availability of dietary polysaccharides. Dietary carbohydrates, specifically resistant starches and dietary fiber (e.g., inulin, fructooligosaccharides), contained in fruits, vegetables, and whole grain cereals are readily fermented by the colonic microbiota to SCFAs, primarily acetate, propionate, and butyrate.

Gnotobiotic mouse models of the human gut microbiota have indicated that linked terminal fucose in host glycans is an attractive and accessible source of energy for members of the microbiota such as the Bacteroidetes.[35]

MICROBIOME VARIATION IN HUMAN POPULATIONS

Awareness of the importance of work on human cohorts is stimulating the boost of comparative metagenomics studies in individuals from different countries, different disease states, and different ages. However, addressing comparative metagenomics studies directly in humans is challenging because of numerous uncontrolled variables, such as genetic variation, geographical, environmental, and dietary differences.

The gut microbiota profile reflects people's country of origin. Yet one of the most prominent differences between human populations prior to world globalization or "Westernization" was diet. Examples included the so-called "Mediterranean diet" characterized by the traditional abundance of olive oil and legumes, or the fish and fat diet of Eskimo population.

The geographical diversity of diet could therefore profoundly explain geographically different microbiota as a result of the interplay of the aforementioned variables.

Several studies analyzed variables such as different geographical locations, diets, and ages. A recent cross-sectional study on intestinal microbiota composition was performed on 230 healthy subjects (two age groups: 20–50 years and older than 60 years) living in four European locations: France, Germany, Italy, and Sweden.[36] The analysis used a set of 14 group- and species-specific 16S rRNA-targeted oligonucleotide probes to analyze fecal samples by fluorescence in situ hybridization coupled with flow cytometer. Age-related differences in the microbiota makeup were detected but differed between the study populations from the four countries, each showing a characteristic colonization pattern. Marked country–age interactions were observed for the German and Italian study groups. These interactions were opposite for the predominant bacterial groups such as *Eubacterium rectale, Clostridium coccoides, and Bacteroides–Prevotella*. Differences between European populations were observed for the *Bifidobacterium* group only. Proportions of bifidobacteria were two- to threefold higher in the Italian study population than in any other study group, and this effect was independent of age. Higher proportions of enterobacteria were found in all elderly volunteers independent of the location. Gender effects were observed for the *Bacteroides–Prevotella* group, with higher levels in males than in females.

The utilization of whole-microbiome sequencing moved these types of population studies beyond a description of microbial species or genes present in particular habitats, linking the structure and dynamic operations of microbial communities reciprocally to human biology and pathobiology.

The MetaHIT consortium published a first paper describing metagenomic data set, using Illumina sequencing technology, containing almost 200-fold more gut microbial sequences from fecal samples of 124 European individuals, including healthy, overweight, and obese adults, as well as patients with IBD.[10] The functional analysis of the gene catalogue identified a core set of genes that seem to be essential for bacterial survival in the gut. These include typical housekeeping genes and others that may encode products involved in adhesion to host proteins or in harvesting the sugars that are carried on blood or epithelial cells. Some functions were present in all 124 individuals included in the study cohort but detected in only a small proportion of previously sequenced genomes of gut bacteria. Therefore, the genes encoding these functions may be essential for the

functioning of the gut ecosystem as a whole but may be encoded across different bacterial species. Recently, the MetaHIT consortium[11] described the worldwide microbiome variation according to a series of distinct enterotypes. This study increases the number of individuals and populations from which gut microbiomes have been sequenced. The authors surveyed the gut metagenomes of 22 European individuals and combined the findings with existing data from Japanese and American individuals. They found that the microbiome clusters into distinct phylogenetic groups (enterotypes), which do not reflect country or continent of origin, body mass index (BMI), age, or gender. Each of these three enterotypes is identifiable by the variation in the levels of one of three genera: *Bacteroides* (enterotype 1), *Prevotella* (enterotype 2), and *Ruminococcus* (enterotype 3). The authors affirmed that enterotypes appear complex, are probably not driven by nutritional habits, and cannot simply be explained by host properties such as age or BMI, although there are functional markers such as genes or modules that correlate remarkably well with individual features. Although these studies infer differences related to different diets, they can hardly describe in detail the actual dietary variables.

Children from different human populations provide an attractive model to study the role of geography and diet on microbiota variation. Infants living in developing countries have been shown to be colonized at younger ages with fecal bacteria and have more rapid transfer of enteric microbial strains than infants living in developed countries.[37]

In our recent work,[38] investigating diet–gut microbiota interaction, we discuss how the ability of modern *Homo sapiens* to live in different environments and to follow a wide range of diets has affected our gut microbial ecology. We characterized the fecal microbiota of 14 African children (BF) living in a rural village (Boulpon, Burkina Faso, Africa) and 15 European children (EU) living in an urban area (Florence, Italy), by sequencing the 16S ribosomal RNA gene, with the aim of elucidating the effects of different diets on gut microbiota. The experimental design includes a “natural” control set, breast-fed children from Burkina Faso and Italy. There are five major advancements. The first key finding is that Burkinabè children cluster separately from Italian children and breast-fed toddlers form a third cluster in between (Figure 23-2A). This can be solely the result of diet. Contributions from sanitation could play a role, but this is indeed minor; in fact, if sanitation or hygiene did cause the difference, then one would expect that breast-fed children would also cluster differently. While we clearly observed that mother’s milk significantly

reduces the differences and that is why the breast-fed children cluster separately, the cluster contains both Italian and Burkinabè toddlers, and this is apart from the other Burkinabè and Italian children. The second key finding is that the BF microbiota was significantly enriched in Bacteroidetes and depleted in Firmicutes compared to their EU counterparts, suggesting a co-evolution of intestinal bacteria with their diet, rich in plant polysaccharides (Figure 23-2B). The third key finding is that the fecal samples from children in Burkina Faso especially differed from the Italian subjects because of the presence of *Prevotella and Xylanibacter* (Bacteroidetes), *Treponema* (Spirochaetes), and *Butyrivibrio* (Firmicutes); all appeared in the African but were not found in the Italian samples. This peculiar microbiota is at risk of being lost in urbanized Africans. We hypothesize that these distinctive bacterial genera might help to extract energy from the polysaccharides in the children's heavier fiber diet. Theses bacteria are capable of fermenting cellulose and xylan through a number of carbohydrate-active enzymes, producing anti-inflammatory effects at the same time. The speculation is that there is a link between these microbes that colonize the human gut and termites as part of the Burkinabè diet. The fourth key finding is that SCFA levels are statistically much higher in Burkinabè children compared with the Italian ones, and the four Burkina-specific species (*Prevotella, Xylanibacter, Treponema, and Butyrivibrio*) have the enzymes needed to digest fibers and produce these beneficial molecules. The presence of these species would allow Burkinabè children to maximize the energy intake from indigestible components by producing high levels of SCFAs that supply the host with additional energy. Normal colonic epithelia derive 60%–70% of their energy supply from SCFAs, particularly butyrate.[39] Propionate is largely taken up by the liver and is a good precursor for gluconeogenesis, liponeogenesis, and protein synthesis.[40] Acetate enters the peripheral circulation to be metabolized by peripheral tissues and is a substrate for cholesterol synthesis.[41,42] Together, they account for 10% of calories extracted from a Western diet each day[39] and probably a more abundant amount of calories in the diet of a typical rural village in Burkina Faso. In addition, SCFAs have several functions: they can reduce inflammation in colitis, promoting tissue renewal[43]; increase the absorption of sodium and water in diarrhea[44]; and regulate enteric neurons and control of GI motility.[45] The last key finding is that biodiversity is significantly reduced in Italian children with respect to Burkinobè children. The different bacterial compositions are likely to have profound influences on another

organ as well as the immune system, possibly explaining the absence of IBDs in African children and adults. Exposure to the large variety of environmental microbes associated with a high-fiber diet could increase the potentially beneficial bacterial genomes, enriching the microbiome. Reduction in microbial richness is possibly one of the undesirable effects of globalization and eating generic, nutrient-rich, uncontaminated foods. Both in the Western world and in the developing countries, diets rich in fat, protein, and sugar, together with reduced intake of unabsorbable fibers, are associated with a rapid increase in the incidence of noninfectious intestinal diseases. The potential protective effects of the diet on bowel disorders was first described by Burkitt[46] who, working in Africa in the 1960s, noticed the remarkable absence of noninfectious colonic diseases in Africans consuming a traditional diet rich in fiber. We extend this observation proposing that this health improvement is the combined result of a fiber-rich diet and microbiota. The speculation regarding the influence of a Burkinabè type of diet in reducing IBD and allergies have to be thoroughly tested in the future, but several independent pieces of evidence link Crohn's disease and allergies to alterations in intestinal microbiota and consequently in immune responses, and the increase in SCFAs that we report in rural Burkinabè children could explain why such diseases that are increasing in the Western world are virtually absent in Africa.

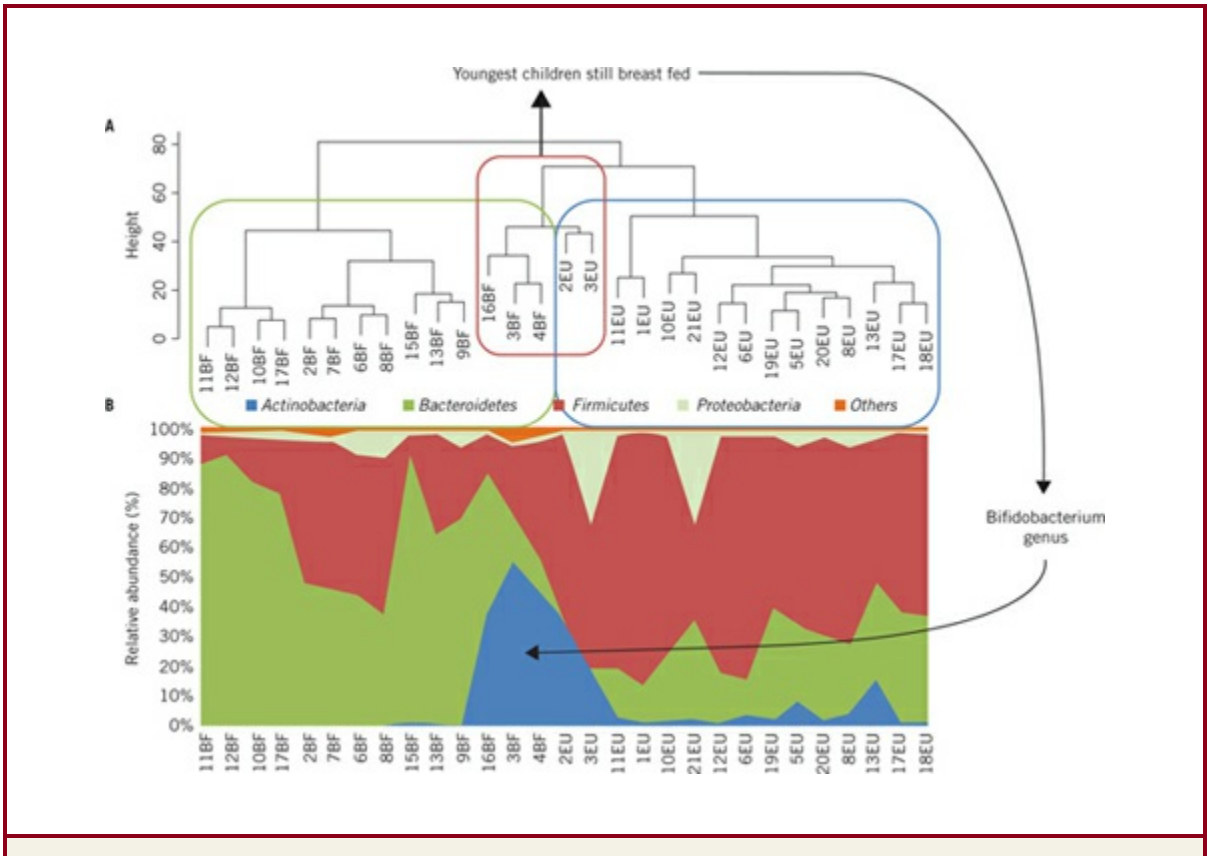

Figure 23-2 (A) Dendrogram obtained with complete linkage hierarchical clustering of the samples from BF and EU populations based on their genera. The subcluster located in the middle of the tree contains samples taken from the five youngest children (1–2 years old) still breast fed (three from BF group and two from EU group). (B) Relative abundances (percentage of sequences) of the four most abundant bacterial phyla in each individual among the BF and EU children. Firmicutes (red) and Bacteroidetes (green) abundances significantly differentiate the BF from the EU children. Blue area in middle shows abundance of *Actinobacteria*, mainly represented by *Bifidobacterium* genus, in the five youngest EU and BF children. BF=Burkina Faso; EU=Italian.

The increased biodiversity and possibly the activation of the immune function could be important also in protection from infections and to outcompete pathogenic bacteria. A diet poor in simple sugars and rich in fibers could in fact explain the marked reduction in potentially pathogenic phyla in the rural Burkinabè children with respect to the Europeans,[38] a paradox if one considers the fact that Burkinabè children drink from polluted water and live in a much less sanitized environment.

Cultural factors, especially diet, may be crucial in shaping the gut microbiota. The ratio of two of the main genera of gut bacteria, *Prevotella* and *Bacteroides*, correlates well with the overall pattern of diversity across healthy adults. Levels of *Prevotella* were enriched in our study on children from a rural African village who had a high-fiber diet, and this phenomenon was confirmed in a study on children and adults from Malawi and Venezuela whose diet was dominated by plant-derived polysaccharide foods such as maize and cassava.[47] By contrast, the microbiota of those in the United States had more *Bacteroides*. For healthy adults in the United States, differences in long-term diet between individuals also were correlated with these bacteria. Bacteroides was associated with a long-term diet rich in animal protein, several amino acids, and saturated fats, and *Prevotella* was associated with carbohydrates and simple sugars. The relative importance of changes in the microbiota as a result of diet, compared with other factors that affect health, remains a subject of active investigation.

DEVELOPMENT OF INTESTINAL MICROBIOTA IN INFANTS AND ITS IMPACT ON HEALTH

Metagenomics research is particularly promising in studies on infants gut microbiota Germ-free while in the womb, babies are exposed to beneficial bacteria in the birth canal and in the anogenital region of the mother's body during and following delivery. Statistically significant reports indicated increased rates of childhood allergies and asthma as related to Caesarean section and the lack of a typical bacterial ecology at birth. Breastfeeding also seems beneficial for bacterial balance. Sartor and Anday in 1987[48] report that formula-fed premature infants are susceptible to necrotizing enterocolitis. Breast milk provides a steady influx of beneficial bacteria (probiotic species such as bifidobacteria and lactobacilli are common in breast milk), with abundant evidence that gut bacteria that colonized early in life induce protective immune responses. The theory is that vaginal birth and breastfeeding help babies to acquire a healthy gut bacterial ecology, which helps the immune system ward off chronic ailments later in life.[49] To date, however, we know little about how the immune system responds to and learns from the successional development of the infant gut microbiota, from sterility before birth to the first early facultative anaerobic colonizers like the Enterobacteria and lactobacilli in the first days of life and later bifidobacteria during breastfeeding and subsequent development of the complex adult-like anaerobic gut microbiota in the young child. These early interactions between the infant's immune system and intestinal microorganisms are critical for development of immune tolerance and for protecting against immune related diseases. The key "educational" processes of exposure to microbial infections as well as appropriate colonization of the gut by a beneficial microorganisms, appears to be critical in the development of immune homeostasis. Importantly, early infections allow the immune system to recognize "friend from foe" by virtue of the fact that pathogenic bacteria distinguish themselves from other microbiota members by invading human tissues, occurring in inappropriate cellular compartments and causing cellular damage that then triggers inflammatory processes. The memory of these early encounters with unfriendly invaders is thought to contribute to the development of a well-functioning immune system, tolerant of the majority of intestinal microbiota members but able to mount rapid and effective inflammatory and antibody responses to invading pathogens. However, we still know very little about how diet, the mothers prenatum and during breast-feeding, and the infants during suckling and subsequently weaning, impacts on these complex interactions between the naive immune system and microbial successional development within the gut. Importantly, most previous studies have focused on only certain often

cultivable bacterial species within the infant gut microbiota or on particular time points in microbiota successional development. Human milk is a source of bacteria to the infant gut, where they may play a variety of antiinfectious, immunomodulatory, and metabolic roles. In fact, recent studies indicate that the human milk contains its own microbiota during lactation.[50] This bacterial community may differ depending on the individual and the health status of the lactating women. It seems that certain bacteria from the maternal gut can use mononuclear immune cells to colonize, first, the mammary gland and, later, the infant gut through breastfeeding.[51] Recently, it has been shown that breast-fed babies have many more Firmicutes bacteria than formula-fed infants.[52] Formula-fed babies have bacterial patterns more similar to adults, with bacterial imbalances, which are being linked to chronic conditions, such as diabetes associated with obesity. The results are indicating that formula probably lacks important components of mother's milk. Other studies have implicated bacteria in type 2 diabetes, which can be a consequence of obesity, reporting that a high-fat diet triggers inflammatory responses in the small intestines and colon long before the animals gain weight.[53] Germ-free animals that don't have bacteria don't get the intestinal inflammation, insulin resistance, or weight gain even when they eat as much fat as regular rats.[54] These researchers also found a strong correlation between bacteria-induced inflammation and insulin resistance, which can lead to diabetes. It is right now widely demonstrated that a bacterial imbalance in our gut plays a role in diabetes, asthma, and allergies. Probably this is just the tip of the iceberg, and the correlations and causations between bacteria and disease are much more than we could predict.

It is estimated that certain periods in life (like the suckling period, introduction of formula and solid foods) offer windows during which nutrition might affect the immunologic development of the young infant. Nutrition may be the source of antigens to which the immune system must become tolerant, provide factors (including nutrients) that themselves might modulate immune maturation and responses, and provide factors that influence intestinal microbiota, which in turn will affect antigen exposure, immune maturation, and immune response.[55] The diverse mixture of bioactive components in human milk influences the immune status of the suckling infant not only by providing protection but also by facilitating the development, tolerance, and appropriate inflammatory response. Maternal milk can be considered as the communication vehicle

between the maternal immune system and the infant.[56–58] The interaction of food compounds with the immune system or indirectly through their effect on the gut microbiota will influence the process of immune maturation and responses.

ROLE OF GUT MICROBIOTA IN OBESITY AND METABOLIC DISEASE

Several studies focused on the ability of different microbiota to differently extract food calories. This trait has indeed been under selection during our evolution; the ability to store energy would be a beneficial attribute for ancient humans who had variable access to food. However, in modern, developed societies, where there is ready access to large portion, high-calorie diets, this benefit becomes a detriment. Many studies described that one manifestation of this symbiotic relationship is microbial processing of components of the diet and deposition the extracted energy in host fat depots. Obesity has reached epidemic proportions in Westernized cultures, and the diseases associated with it, including insulin resistance and type II diabetes mellitus, hepatic steatosis and steatohepatitis, dyslipidemia, and atherosclerotic cardiovascular disease, have become major public health problems.[59] Traditional obesity research has focused on environmental and host genetic factors, including descriptive studies in humans and mechanistic studies using genetically altered rodent models.[60] More recently, research over the last five years using culture-independent methods and NGS has suggested that the pathogenesis of obesity may be influenced by our endogenous gut microbiota.[61–65] A fundamental breakthrough came from 16S rRNA–based analysis of community structure (phylotype abundance distribution) associated to sequencing of fecal microbial communities (metagenomics) of obese and nonobese adult human twins, and their mothers.[2,22,62] Family members had considerable overlap in their gut microbial communities, with the degree of variation being similar between monozygotic and dizygotic twin pairs. Notably, however, obese individuals showed an impressive overall reduction in microbial diversity. One of the most striking results was an altered balance of the ratio between Bacteroidetes and Firmicutes, the two major phyla commensal bacteria residing in the GI tract. An important metabolic difference between these two phyla is the efficiency of energy extraction from undigestible dietary carbohydrates. Therefore, alterations in their relative ratio can result in increased energy accumulation, which is of

special concern in certain pathological conditions. For this reason, several studies have focused in recent years on the composition of human gut microbiota in obese subjects under different dietary regimens.[22,65] The authors liken this reduced diversity to a fertilizer runoff, in which a subset of the microbial community blooms in response to abnormally high-energy input, as opposed to the rainforest- or reef-like community of the lean gut, which displays high species diversity in the face of high-energy flux.

To selectively test the role of microbiota in obesity animal, models have been used as a controlled system to investigate the role of dietary changes on microbiota.[35,63,64]

"Top-down" systems biology comparisons of metabolic profiles of normal human and mice microbiota revealed that absorption, storage, and metabolism of dietary lipids were specifically modulated by the microbiome.[66,67] Moreover, the induction of type 2 diabetes and obesity with a high-fat diet in rats has been shown to correlate with preexisting metabolic patterns associated with differences in gut bacterial activities, indicating causality between microbiome and host predisposition to diseases.[68]

Changes in the gut microbiota of humanized gnotobiotic mice have been studied after the mice are switched from a diet low in fat and rich in plant polysaccharides to a Western diet high in fat and sugar and low in plant polysaccharides.[35] After just one day on the Western diet, mice show changes in their microbial composition, metabolic pathways, and gene expression, and within two weeks they develop more adiposity. Mice on a Western diet show an increase in bacteria of the Firmicutes phylum and a decrease in those of the Bacteroidetes phylum.

These concepts represent an important paradigm shift in understanding health conditions and disease and are likely to have a significant impact on the future of the prevention and therapy of intestinal diseases.[66]

Despite the advantage of selectively and precisely controlling all the variables, mice seems to be a questionable model for studies on human gut microbiota. The conclusions obtained from animal models or from a handful of human individuals can be hardly generalized to human populations.[68]

The challenge we face now is to understand how the different environments and wide range of diets that modern humans around the world experience has affected the microbial ecology of the human gut.

PROBIOTICS AND GUT MICROBIOTA MODULATION

A number of functional foods have been developed with the aim of altering or modulating the human gut microbiota. Probiotics are live microorganisms, which when administered in adequate amount confer a health benefit on the host.

Probiotics as defined by the World Health Organization in 2001[69] are a relatively recent phenomenon. In that, the first commercial preparations appeared in France and Japan in the early 1900s and 1930s, respectively, and aim to improve host health by adding exogenous microorganisms, usually lactic acid bacteria, bifidobacteria, or the yeast *Saccharomyces boulardii* to the hosts' gut microbiota and are gaining scientific backing for protective capabilities against a number of chronic human diseases and GI infections. However, "probiotics" in the human diet probably goes back much further, with long histories of using very similar microorganisms for fermented milk, meats, and cereals going back to the beginnings of agriculture and touching on the "hygiene hypothesis" or "old friends hypothesis,"[70] which endow the health benefits through appropriate education of the immune system in infancy and lifelong regulation of immune homeostasis by regular and diverse interactions with environmental, including food, microorganisms, both beneficial or benign, and those responsible for minor infections. Since modern probiotics do not colonize the human gut microbiota and only on a few occasions have been shown to alter mammalian metabolic processes, the likely mechanism of probiotics effect is through the immune system.[71] Thus, far from being a modern invention of the food industry, probiotics and the probiotic principle has a long history and is part of wider scientific paradigm describing our continued connection with the natural world through the microorganisms we eat, our gut microbiota and our highly evolved immune system.[70]

"A prebiotic is a selectively fermented ingredient that results in specific changes in the composition and/or activity of the GI microbiota, thus conferring benefit(s) upon host health" and represents another functional food approach toward modulating the composition of the human gut microbiota.[72] These fibers, which are selectively fermented by the human gut microbiota, again although recently defined as modern food ingredients, have a scientific basis at the core of gut microbiota functionality, saccharolytic fermentation with its resultant production of SCFAs, and changes within the relative abundance of bacteria known to

play important roles in immune-homeostasis, lipid/fat metabolism, regulation of mucosal integrity, and vitamin production, most notably, the bifidobacteria.[73] Interestingly, certain whole plant foods, especially whole grain cereals are proving to mediate the same alterations within the composition and activity of the human gut microbiota as these modern prebiotic food ingredients, fitting well what we know about the health benefits of both prebiotics and whole grain cereals especially in biomarkers of metabolic health such as blood cholesterol levels.

Nutrition and 24 Neuropsychological Development

Maureen M. Black, PhD and Kristen M. Hurley, PhD

Nutritional deprivation is a worldwide public health concern that can result in long-term deficits to children's growth and development. Two series of papers in *The Lancet* on global child development found that more than 200 million children under 5 years do not reach their developmental potential, largely due to poverty, chronic undernutrition (stunting), micronutrient deficiencies, and lack of early stimulation.[1–5] Delayed development early in life increases the likelihood of neuropsychological problems, poor school performance, and subsequently low income-generating potential, high fertility, and poor caregiving capacity, thus contributing to the intergenerational transmission of poverty. However, early home and center-based programs targeted toward young disadvantaged children throughout the world can disrupt the negative cycle and contribute to positive effects on children's neuropsychological development, academic performance, and life chances.[4]

This chapter examines the relationship between nutritional deficiencies and neuropsychological development in children. It reviews the history of research linking nutrition and children's development, methods used to study child development, and the evidence linking nutrition and child development, with an emphasis on micronutrient deficiencies. Finally,

recommendations are made to reduce the burden that children experience from nutritional deficiencies.

HISTORICAL CONSIDERATIONS

The association between nutritional deprivation and child development has been a topic of interest for over 40 years. Initially, investigators focused on protein-energy malnutrition (PEM), caused by a lack of calories. During the acute phase of nutritional deprivation, children have been described as lethargic, apathetic, and inactive, with poor performance on measures of cognitive functioning.[6]

Research on PEM has focused on the long-term consequences associated with early nutritional deprivation. Guided by findings from animal research that nutritional deprivation can lead to structural and functional changes in the developing brain,[7] investigators have used a variety of standardized assessment tools, such as intelligence quotient (IQ) tests or behavioral rating scales, to determine whether nutritionally deprived children recover or experience long-term neurobehavioral consequences. Case-control, retrospective designs have been used to study children with a history of nutritional deprivation and compare their task performance with that of adequately nourished children. Findings generally indicate long-lasting deficits in intelligence and school performance.[6]

Nutritional deprivation often occurs in the context of poverty. Although most investigators handle socioeconomic differences in study populations by recruiting comparison children from similar socioeconomic backgrounds, little attention has been directed to individual differences or how children's response to nutritional rehabilitation varies by environmental characteristics. Advances in the areas of growth, nutrition, animal research, behavioral neuroscience, and child development have influenced recent investigations of nutritional deprivation and child development.

Growth

In the absence of adequate nutrients, the body may conserve energy by initially limiting weight gain and subsequently limiting linear growth. Linear growth or height is influenced by genetic factors, environmental factors, and medical conditions. In 2006, the World Health Organization (WHO) published international growth standards from the Multicountry

Growth Reference Study, which examined how healthy children grow in homes that engage in health-promoting practices (breastfeeding and not smoking). Approximately 8500 children from varying ethnic and cultural groups in six diverse countries (Brazil, Ghana, India, Norway, Oman, and the United States) participated in the study. Children were measured from birth through age 5 years. There was strong similarity in linear growth across the six sites, providing evidence for the use of a single international growth standard and demonstrating that when children's health and environmental needs are met, growth is similar.[8]

Stunting, defined as children who fall below −2SD from the length- or height-for-age WHO Child Growth Standards median, serves as a general indicator of children's chronic nutritional status. Growth stunting is a gradual process that occurs in response to chronic biological insults, including undernutrition and infectious diseases, during periods of linear bone growth. It often begins in utero and extends through the first 2 years, commonly referred to as the first 1000 days.[9] Childhood stunting is closely associated with poverty and is often used as a population-based indicator to compare nutritional adequacy across countries. Early stunting can disrupt permanent growth, resulting in shorter stature among adults with a history of stunting. Recent evidence from United Nations Children's Fund (UNICEF), WHO, and the World Bank, based on 2011 data from 639 national surveys from 142 countries finds that 26% of children under age 5 years (165 million) are stunted (height-for-age Z score of −2 or lower). This figure is a dramatic decline from surveys conducted in 1990, which estimated rates of stunting of 40% (253 million children). Changes in the rates of stunting reveal marked inequalities, particularly related to economic indicators.[10] The highest prevalence of stunting occurs in Africa, but the greatest number of children affected is in Asia.

Mounting evidence from multiple countries suggest that children who experienced nutritional deprivation severe enough to cause stunting early in life have cognitive deficits during school-age years that can interfere with successful academic performance.[4,5] Early stunting undermines children's long-term performance and has been used as an indicator to estimate the number of children worldwide who do not reach their developmental potential.[3]

Animal Research

Animal models have been widely utilized in research linking nutrition to cognitive functioning. Much of the neurological development of rats

occurs postnatally, enabling investigators to study the timing and chronicity of nutritional deprivation.[7] However, many of the techniques used to introduce nutritional deprivation (e.g., increasing the number of infants for a mother to feed, decreasing access to the mother, etc.) altered mother-pup interaction and the social environment, thus confounding the research. Through innovative designs, such as the introduction of artificial feeding, investigators have been able to vary both nutritional intake and environmental stimulation.[11] Animals who experience both nutritional and environmental deprivation tend to have worse performance than animals deprived in only one condition, suggesting that the environmental stimulation may attenuate the adverse consequences of undernutrition.[12] Levitsky and Barnes[13] described the process whereby nutritional deficiencies may alter caregiving behavior as *functional isolation* (Figure 24-1).[13] Thus, in addition to the direct effects of nutritional deprivation, undernourished animals may also be denied the environmental enrichment that promotes development.

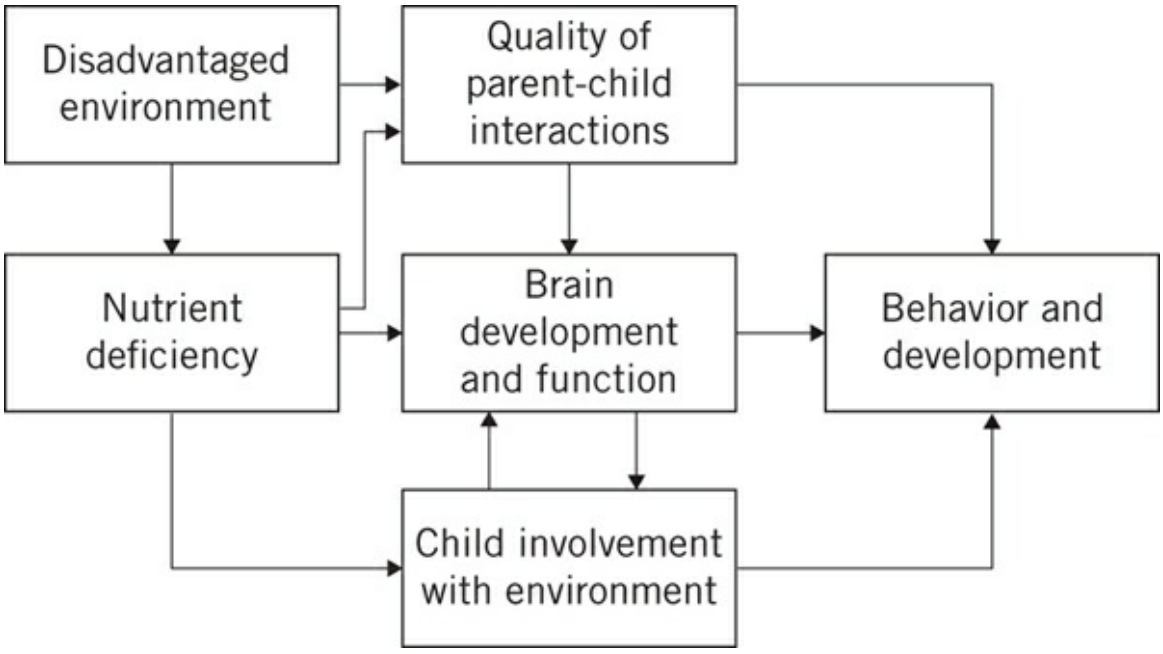

Figure 24-1 Association between nutritional deficiency and children's behavior and development. Adapted from Levitsky and Barnes.[13]

The timing of nutritional deprivation has been a particularly relevant question because early investigations were guided by the sensitive period

hypothesis that developing organs deprived of essential nutrients would experience irreversible structural damage.[7] Although some changes induced by nutritional deprivation remain following rehabilitation, particularly related to myelin (the fatty substance that surrounds nerve cells and aids with transmission), neuronal mitrochondria, and neurotransmitter metabolism,[11] many structural changes can be reversed with nutritional rehabilitation.[14] Evidence suggests that there may be metabolic or neurochemical consequences of nutritional deprivation.[11]

Rehabilitated animals with a history of nutritional deprivation appeared to be at risk for changes in their emotionality, motivation, anxiety, and cognitive flexibility, evidenced by behaviors such as increased spilling, hyperreactivity, and increased aggression. These behaviors may interfere with performance on cognitive tasks, suggesting that early undernutrition may alter neurochemical-receptor systems, resulting in an inability to adapt to novel or stressful situations.[14]

Behavioral Neuroscience

Advances in behavioral neuroscience have shown the important role that experiences on brain development, particularly with respect to pruning, myelination, and synaptic formation.[15] Brain development begins prenatally and continues through adolescence (Figure 24-2).[16,17] It begins with the formation of brain cells, followed by cell migration and differentiation, and the development of synapses to enable cells to communicate with one another. Finally, the supportive tissue (myelin) is formed to protect the nerve cells and facilitate communication.[17,18]

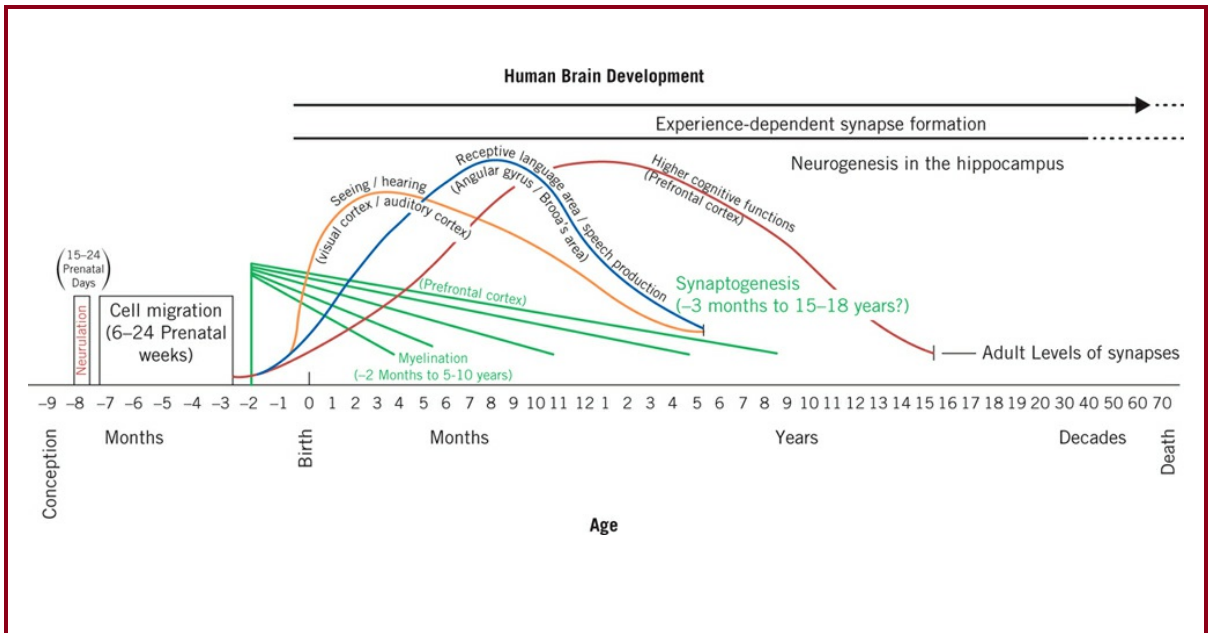

Figure 24-2 Human brain development. Adapted from Thompson and Nelson.[16]

The process of forming and eliminating synapses occurs throughout the developmental period and is influenced by two types of experiences: experience-expectant and experience- dependent.[18] Experience-expectant refers to species-specific development, including maturational influences that guide early sensory and motor development, such as the specific roles played by nutrients in altering cell function and structure through neurochemical changes within the cells. Experience-dependent occurs throughout life as individuals adapt to specific cultural and environmental demands and opportunities. The structural changes in synaptic formation are dependent on neurochemical- receptor systems that, in turn, are influenced by experiences as basic as caregiving.[18]

The timing of early developmental experiences has been a central issue in studying behavioral neuroscience. The critical or sensitive period hypothesis suggests that if an event, such as nutritional deprivation, occurs during a period of rapid development, such as the first 1000 days, it may have long-lasting impact on the organism.[7]

Recent evidence suggests that although the first 1000 days (conception to 24 months of age) is a sensitive period in children's development, it is not the only sensitive period.[19] Children's development is characterized by multiple sensitive periods, depending on specific structures or functions. For example, adolescence is a sensitive period for the ongoing development of the prefrontal cortex, vulnerability to stress, and aspects of executive function, perspective taking, and abstract reasoning.

Child Development

Child development is defined here as the orderly progression of skills that children acquire as they mature and adapt to their specific caregiving settings. Although there are universal aspects of child development, particularly early in life as children gain motor skills and learn to roll over, sit, stand, and walk, there are also individual and cultural differences in the acquisition of skills. For example, children learn to understand and speak the languages they hear in their household.

The recognition that the link between nutritional deprivation and neuropsychological development depends on nonnutritional factors and can be influenced by environmental stimulation has had an important impact on research involving nutritionally deprived children. Caregiving

variables, such as the quality of parent–child interaction, have been incorporated into models of child development, moving away from models that merely control for socioeconomic differences.[20,21]

A transactional system approach provides a useful framework for understanding the link between nutrition and early child development because it emphasizes the interplay that occurs between children and their environment, mediated through relations with their caregivers (Figure 24-3).[22,23] Children's development is influenced by characteristics from the child (e.g., nutritional status), from the caregiver (e.g., maternal education), and from interactions between the child and caregiver (e.g., reciprocity and clarity of communication during feeding).

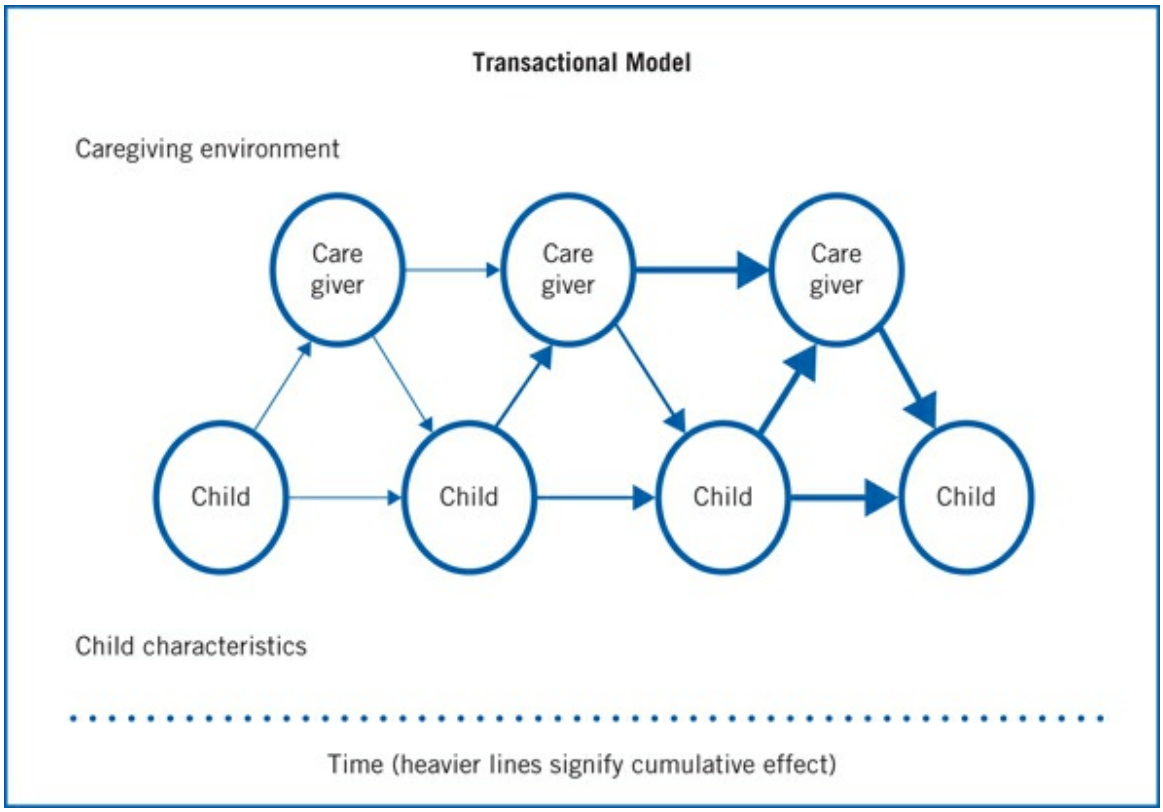

Figure 24-3 The transactional model.

The transactional system forms the theoretical basis for responsive parenting and responsive feeding.[24] Responsive feeding emphasizes the interactive nature of feeding, whereby caregivers set guidelines and gage their reactions to the signals they read from their children, ideally resulting in a respectful give-and-take (serve-and-return) exchange around feeding,

resulting in healthy mealtime behavior and a healthy weight gain.[25] Unresponsive feeding interactions may be characterized by negative, coercive strategies to promote eating or by permissive, overindulgent strategies, such as making food available throughout the day or providing favorite foods with little regard to quality. These strategies are likely to undermine children's appetite, increasing mealtime stress as children hold out for snacks.

The transactional model may also form the basis for intergenerational transmission of disparities. For example, a woman who is undernourished during her pregnancy and does not receive prenatal care is at increased risk to give birth to an infant with low birth weight (LBW) (<2500 g). In comparison with full-term infants, LBW infants are smaller and often have weaker cries and sucking skills.[26] These characteristics make infants with LBW more difficult to feed, particularly for mothers who are undernourished themselves. A cycle emerges whereby the small, weak infant is difficult to feed, does not grow well, may be vulnerable to illnesses, and lags behind in developmental skills. Mothers may feel frustrated and/or frightened by their infants who are small and sickly and may limit their caregiving to holding, rather than talking or encouraging exploration.[27] This process results in a negative cycle whereby infants do not elicit or receive the care and attention they need to promote optimal development, a human example of functional isolation.

Intervention can occur at multiple points within the transactional system.[23] For example, intervention could be directed to the infant with LBW, perhaps through nutritional and developmental intervention that might be available through community nutrition programs, or through early intervention programs. If the child's growth and development improve, the child will be more likely to elicit and receive age-appropriate care and interaction from the caregiver.

Intervention could also be directed toward the caregiver and the interaction between the caregiver and the child. Children's cues can be targeted to ensure that the caregiver understands how the child expresses hunger or satiety, and can read and respond to the child's cues. Using components of the transactional system to promote the development of undernourished children has been a successful strategy.[1,2]

Although, most of the attention has been directed to the impact of inadequate nutritional and caregiving practices on children's nutritional status, children may influence caregiver behavior through their nutritional status, as predicted by the transactional system. Children with PEM have

been described as negative, wary, and lethargic.[28] During home observations, mothers of undernourished infants have been described as less sensitive and responsive than mothers of healthy infants,[29] and tended to hold or carry them, rather than play with them.[27] Caregivers who treat their infants as though they are ill or unable to participate in age-appropriate activities may be inadvertently denying them opportunities for developmental stimulation and enrichment.

In one of the only studies to observe caregiver-child interaction prior to the child's becoming undernourished, investigators in Mexico reported that infants of mothers who lacked sensitivity and affection were more likely to become undernourished, compared to infants of more sensitive mothers.[30] In turn, after infants received nutritional supplements, their mothers were more engaged, both in caregiving and in enrichment activities, compared with mothers of nonsupplemented infants, suggesting that mothers respond positively to their infants' increased energy and activity.

METHODOLOGY

Most research examining associations between early nutritional deprivation and subsequent intellectual skills has been retrospective and observational, with little attention to differences in environmental or caregiving factors. This section examines the choice of outcome and predictor variables, and a consideration of environmental and caregiving variables that may confound findings.

Childhood Measure of Intelligence

The primary outcome measures used in studies of recovery from nutritional deprivation have been generalized tests of intelligence administered during the school-age years, such as the Wechsler Intelligence Scale for Children (WISC). The WISC is a standardized assessment that yields an IQ that is stable over time and predicts both academic performance and occupational status.[31] Although many other factors contribute to academic performance and occupational success (e.g., motivation), the IQ is a useful indicator of successful rehabilitation.

Infant Measures of Development

Infancy is marked by rapidly changing skills, discontinuities in early development, and limited performance options. Early measures of infant

development often focus on sensorimotor processes.

General Tests of Intelligence

Investigators have used either generalized tests of infant intelligence, such as the Bayley Scales of Infant Development Third Edition (Bayley III), or specific information processing tests. The Bayley III is a well-standardized assessment for infants aged 1–42 months that includes three scales administered by trained examiners: cognitive, language, and motor, and two scales completed by caregivers: socioemotional and adaptive behavior.[32] The Bayley III was designed to determine if infants are able to complete age-normed tasks, not to predict future functioning.[32] It has been used globally and has excellent psychometric properties, with internal consistencies measured by coefficient alphas averaging 0.86 and above, and test-retest reliabilities ranging from 0.72 to 0.81 across all ages. Correlations from infant assessments administered prior to 18–24 months of age to later intellectual performance vary and are often improved by models that include socioeconomic variables, such as maternal IQ or education.[33] The low correlations between scores from the Bayley III and specific information processing tests, such as visual habituation and attention to a novel stimulus, suggest that they are tapping specific areas, with the higher order functioning measured in the Bayley III incorporating motivation, attention, and multiple cognitive processes.[34] Beyond age 2, once infants gain symbol formation skills, predictability from infant assessments to subsequent intellectual performances increases.[33]

Information Processing

Several information processing tests administered during infancy (e.g., visual attention, learning, and memory) are predictive of school-age intellectual performance.[35] The paired comparison test has been used to assess short- and long-term visual recognition memory.[36] It includes two phases: familiarization and test. During the familiarization phase, two identical stimuli are presented and the infant has an opportunity to view them. During the test phase, a familiar stimulus is paired with a novel stimulus. The observer notes the proportion of time the infant gazes at each stimulus. Since infants are likely to spend more time gazing at the novel stimulus, a novelty score is calculated by dividing the amount of time the infant looked at the novel stimulus by the time the infant looked at both stimuli. The percentage of infant visual fixation to a novel stimulus from the Fagan test is a widely used indicator of infant visual recognition

memory.[37]

Other infant processing tests include focused attention (concentration devoted to processing information about an object),[38] cross-modal transfer (transfer of learning from one sensory modality to another),[39] and the A-not-B task (a Piagetian task that examines object permanence).[40] Although there has been limited use of infant information processing tests related to infants' nutritional status, they may be helpful in understanding links between nutrients and specific processes. As examples, undernourished infants (5–12 months of age) from India had difficulty with two tasks related to cognitive processing—visual recognition memory and cross-modal transfer,[39] the performance of infants from Chile on the Fagan Test varied by their iron status,[41] and there were no effects of iron-folic acid or zinc supplementation on either the Fagan test or the A-not-B test among infants in Nepal.[42] Most investigators recommend that tasks be selected to assess specific processes and that multiple measures be used, beyond IQ, to gain a comprehensive understanding of how nutritional deprivation and recovery impact processing skills.[33,36]

Measures of Social Emotional and Motor Development

The Ages and Stages Social Emotional questionnaire is frequently used to screen for social and emotional behavior. It is a validated caregiver-completed questionnaire organized into age-appropriate categories.

Undernutrition can have a negative impact on motor development, leading investigators to examine how nutritional interventions affect motor development, measured by standardized tests, such as the Bayley III or the Alberta Infant Motor Scale; maternal reports of the acquisition of motor milestones; or observation. Although motor development promotes independence and potentially advances cognitive development by enabling children to explore their environment, the implications of small differences in the timing of early motor development on intellectual functioning are not clear.

Measures of Brain Function in Children

In recent years, there has been an increased emphasis on the neurophysiological and neuropsychological development of children in response to environmental conditions. An increase in the sophistication of measures used to assess the structure and functioning of the brain allows for an improved understanding of the developmental effects of nutritional deficiencies. Optimal brain development during childhood relies on the

intake of specific nutrients such as fatty acids, proteins, and carbohydrates. Specifically, lipids and proteins are needed for adequate cell membrane formation, neurotransmitter release, and myelination, which enhance neuronal efficiency and processing speed throughout the central nervous system. Carbohydrates also appear to play a key role in the regulation of the hypothalamic- pituitary-adrenal (HPA) axis as it relates to food intake under stressful conditions.[43]

The ability to assess the brain functioning of children has improved substantially in the past decade. Electrophysiological techniques, event-related potentials (ERP), functional magnetic resonance imaging (fMRI), near-infrared spectroscopy (NIRS), diffusion tensor imaging, and magnetic resonance spectroscopy (MRS) may be effective methods for determining associations between nutrition and brain functioning. Each assessment method possesses strengths that make it amenable to particular research questions regarding neurodevelopment.[44,45]

Electrophysiological techniques involve the measurement of electric signals in the body and are generally superior to brain scanning techniques in terms of temporal resolution (when activity in the brain occurs in response to an event), but typically possess poor spatial resolution (where in the brain activity occurs). Since active neurons transmit electric signals through brain tissue, this activity can be recorded by electrodes placed on the scalp surface. Voltage distribution and synchronization are measured by numerous electrodes. Measurement of electrical activity is typically time-locked to a specific sensory or cognitive event and averaged over many trials to determine how the brain usually responds to a certain stimulus. ERP studies may be particularly useful in assessing infants and very young children because they do not depend on motor activity and children do not have to remain perfectly still as with most scanning techniques. As such, ERP recordings are an effective way to assess ongoing brain activity correlates in young children.[45]

Functional MRI is an alternative technique used to identify the location of neural activity. When a specific area of the brain is activated, blood flow to that area increases and oxygen is created. Because oxygenated and deoxygenated hemoglobin behave differently when pulsed with a magnetic field, this contrast in oxygen can be mapped onto consecutive “slices” of the brain. The MRI scanner determines the areas of greatest activation. The fMRI procedure has been used with older children and adults to study the location of neural activity. Using fMRI in combination with behavioral, cognitive, or neuropsychological assessments can provide detailed information about the activation of specific brain regions in

response to certain tasks. Limitations are that hemodynamic response is relatively slow (several seconds) in comparison to ERP techniques (milliseconds); fMRI scanning requires the child to be still, making it appropriate only for children who can be trained to remain immobile; and the cost of fMRI is high. NIRS provides noninvasive assessments of cortical functional connectivity by measuring changes in blood hemoglobin concentrations associated with neural activity. Although NIRS can be portable and used with infants because it does not require the subject to be still, it cannot measure deep structures.[44]

Diffusion tensor imaging (DTI) and MRS represent recent advances in neuroimaging that may be particularly relevant for research involving the neurodevelopmental effects of nutrition. DTI is a technique based on magnetic resonance imaging that produces functional images of the location, orientation, and activity of the brain's white matter tracts. DTI reveals the integrity of white matter tracts that link regions of the brain to each other by assessing water diffusion in the axons and their myelin sheaths.[45] Clinical research applications of DTI involve the localization of white matter lesions and the assessment of the white matter maturation in children.[46] For example, deficiencies in nutrients such as iron or essential fatty acids can interfere with myelination in preterm infants.[47] DTI technology is likely to be increasingly utilized to determine associations between nutritional intake and the efficiency of axonal connections throughout the brain.

MRS goes beyond providing information about tissue water content and provides data regarding the chemical nature of a brain region distinguishing the properties of one area relative to those of surrounding areas. MRS can assess the concentration of common metabolites and biological compounds giving important information about glial processes, membrane phospholipids, and high-energy phosphates.[48] Changes in these chemical compositions could be monitored following dietary supplementation throughout a child's postnatal development or after a period of nutritional deprivation.[44]

STRESS AND NEURODEVELOPMENTAL PROCESSES

Nutritional deprivation frequently occurs in the context of poverty, highlighting the need to consider how contextual variables, including environmental stress and caregiving behavior, relate to brain development.

Although brief periods of moderate stress allow children to develop appropriate stress responses,[49] exposure to high levels of stress (toxic stress) early in life during periods of rapid brain development can lead to numerous physical and developmental problems.[49]

The neurobiological mechanisms proposed to account for the cognitive deficits that occur in children with a history of undernutrition include deficits in the nutrients necessary for adequate physical growth and functioning as well as dysregulated HPA axis functioning.[50] The HPA system coordinates the stress response through multiple mechanisms resulting in the eventual release of glucocorticoids (cortisol) from the adrenal cortex. The brain is rich in receptors for cortisol with concentrations noted in the hippocampus and hypothalamus, prefrontal cortex, amygdala, and anterior cingulate gyrus. As excessive cortisol can impair brain regions housing cortisol receptors, intact HPA regulation is important for early development and ongoing maintenance of cortical systems involved with emotion, learning, memory, and attention and impulse control.[21,51,52]

In addition to an inadequate and/or inconsistent food supply, undernourished children often experience a lack of positive interactions with their primary caregivers. Effective caregivers play a critical role in helping children to modulate their emotional and physiological response to stressful events.[21] In the absence of positive interactions and stimulation, children may experience deficits in the development of their stress-sensitive regulatory systems. If they are also undernourished, they may be in a position of double jeopardy. An overexposure to stress in combination with disruptions in HPA axis functioning may be harmful to children's neurodevelopment. Heavily secreted neuroendocrine agents associated with chronic stress produce neurotoxic effects that may damage the developing brain, especially in areas rich in glucocorticoids such as the hippocampus, corpus callosum, and areas of the prefrontal cortex. Children who are repeatedly exposed to stress in the absence of supportive caregiving are at a higher risk for being chronically hyper-aroused to aspects of their environment, with possible negative effects on their attention and executive cognitive processes.[21,52]

In summary, a nonresponsive caregiving environment may undermine children's neural development.[53] The combination of nutritional and caregiving risk factors early in life may place undernourished children at risk for negative cognitive outcomes, possibly mediated by poorly modulated stress reactivity.

ENVIRONMENTAL AND CAREGIVING FACTORS RELATED TO NUTRITIONAL DEPRIVATION

Nutritional deficiencies often occur in a context of poverty among families who have few economic resources and limited education. Not only do many low-income families have restricted access to nutritionally healthy food, but mothers who are poorly educated are less likely to choose nutritionally appropriate foods for their children, compared with better educated mothers.[54] Thus, poverty and factors associated with poverty, such as low maternal education, may have a direct effect on children's development.

Caregivers contribute to their child's development through their care practices, such as providing food and basic care required by young children.[55] In the past, much attention regarding care practices was directed towards defining the quality and quantity of food that children require. However, evidence has demonstrated that care practices play a role in children's development that extends beyond the provision of food. Care practices include the relationships that caregivers form with their children during feeding and other daily activities.[24] Health care practices include behavior that is responsive to children's needs and is characterized by warmth and affection.

Care practices that influence children's nutritional status can be disrupted by conditions such as maternal mental health problems (e.g., symptoms of depression). For example, a recent meta-analysis found young children of caregivers with depressive symptoms were at significantly increased risk for stunting and underweight.[56] Maternal depression is a global public health concern, with potential risks for the health, nutritional status, and development of young children.[57]

BREASTFEEDING

The American Academy of Pediatrics and the WHO recommend exclusive breast milk for infants during the first 6 months and continued breastfeeding for at least the first year of life.[58,59] While the health and immunological benefits of breast milk for children are well established,[58,60] the effects of breast milk on children's development is less clear. Multiple methodological problems interfere with interpretation of studies that examine associations between breastfeeding and subsequent child development. Maternal factors associated with breastfeeding (e.g., intelligence, motivation, responsivity, and education) are also associated

with child development, the definition of breastfeeding varies across studies, and most experimental designs related to breastfeeding would be unethical. Thus, most breastfeeding studies cannot separate motivation and behavioral factors from the nutritional aspects of breast milk on infant growth and development.

A recent trial in Belarus involving over 13,000 infants overcame the ethical dilemma by randomizing breastfeeding promotion at the hospital level.[61] Infants in the experimental condition were exclusively breastfed longer and at age 6.5 years had higher cognitive scores based on standardized tests and higher academic performance based on teacher reports than children in the control condition. Further studies are needed to confirm and explain the relations between breastfeeding and brain development.

LONG-TERM CONSEQUENCES OF EARLY NUTRITIONAL DEFICIENCIES

Information on the long-term consequences of early nutritional deficiencies is available from several natural experiments, including nutritionally deprived children adopted into middle-class families or nutritional deficiencies occurring among children from middle-class families caused by disasters or chronic illness. In addition, information is available from follow-up studies of children from low-income countries who experienced moderate to severe nutritional deprivation or children from middle-income countries who experienced mild nutritional deprivation. However, data on the long-term consequences of early nutritional deficiencies can be difficult to interpret because children who experience nutritional deficiencies are often raised in low-income families where they also experience environmental deficiencies.

Natural Experiments

Female orphans from Korea who varied in their nutritional status, were adopted by middle-class American families, and tested during their school-age years. The children who had been undernourished early in life achieved scores in the normal range, but lower than those of better nourished Korean adoptees (Figure 24-4).[62] Although these findings demonstrate the impact of an enriched environment on children's intellectual skills, they also suggest that early nutritional deficiencies may limit children's ability to benefit from an enriched environment.

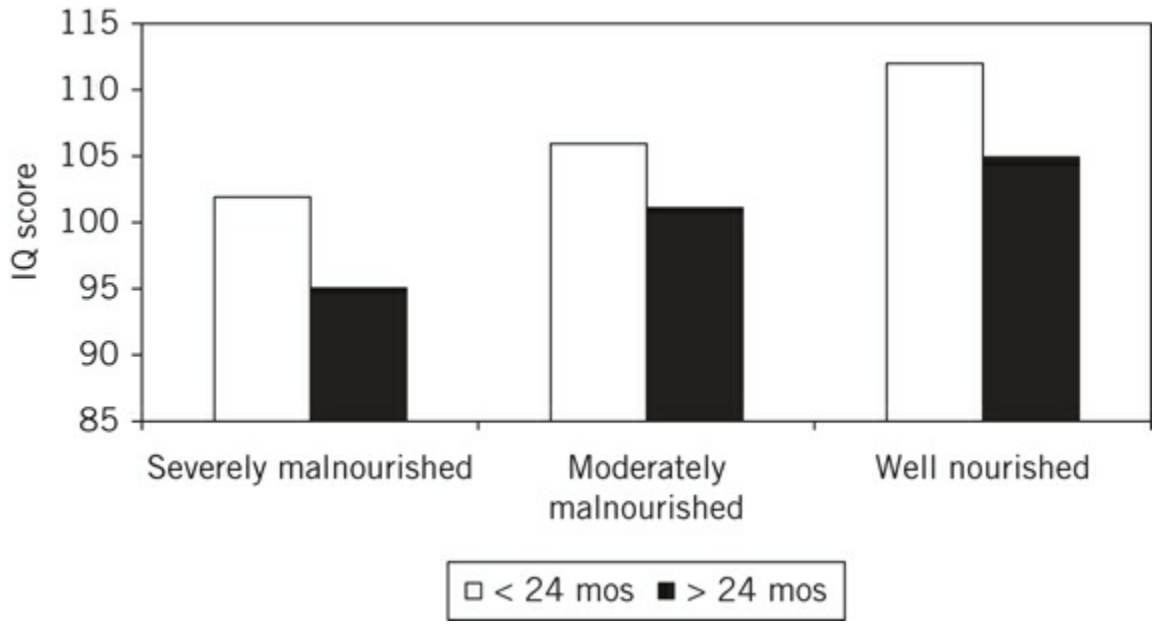

Figure 24-4 IQ scores among female Korean orphans varying by history of undernutrition and age of adoption. Adapted from Winick.[62]

The 1944 famine in Holland affected the entire population, regardless of economic standing. When the youth who experienced the famine were tested at 19 years of age as part of an army physical there was no long-term evidence of intellectual deficiencies, compared with scores from nonfamine years.[63] These findings suggest that environmental opportunities had overcome deficiencies associated with the early nutritional deficiencies.

However, recent evidence has shown that the children of mothers who suffered nutritional deprivation during the Dutch famine experienced reduced cognitive function and multiple health risks, including cardiovascular, vascular, and metabolic problems.[64] These findings suggest an epigenetic effect related to prenatal nutritional deprivation.

Children with chronic diseases, such as cystic fibrosis, are at risk for undernutrition due to malabsorption. Long-term consequences varied by family income. Among children from middle-income families, there were no differences in school-age intellectual scores, based on nutritional history.[65,66] In contrast, among children from low-income families, those with a history of nutritional deficiencies secondary to chronic disease had lower scores than those who had been hospitalized, but were well nourished. These studies illustrate the buffering effects of a nurturing

environment on the intellectual performance of nutritionally deprived children.

LONG-TERM CONSEQUENCES OF MILD NUTRITIONAL DEFICIENCIES

Findings on the long-term consequences of children from middle-income countries diagnosed with early growth faltering (failure to thrive) add to our information on nutritional deprivation and cognition. Although there are no agreed upon criteria for the diagnosis of failure to thrive, the term is generally used to describe children under age 3 years who have experienced a deceleration in growth over time, such that their weight-for-age or weight-for-height is below the fifth or third percentile.[67] Children with early growth faltering usually experience mild forms of deficiency, compared to children identified with nutritional deficiencies in low-income countries. During infancy and toddlerhood, the cognitive scores of children with growth faltering are lower than scores of comparison children with adequate growth, and often remain low through the preschool period.[68,69]

Follow-up studies of infants with growth faltering in infancy report that by age 13 their growth is within the normal range, but the rate of growth varies depending on the timing of the early weight faltering.[70] At school-age, children with a history of early growth faltering differ from children with a history of adequate weight gain by approximately 4 IQ points,[71–73] but in one of the only studies to follow children into adolescence, any educational differences could be explained by confounding.[74]

The relationship between nutritional status and cognitive functioning is often mediated by family, environmental, and cultural variables,[75] making the family an ideal context for prevention of the negative consequences of growth faltering. An intervention trial among children with early growth faltering found that after 1 year infants who received the home intervention had a more child-centered home environment, better cognitive scores, and better expressive language scores, compared to infants who did not receive the home intervention.[68] At age 8, beneficial intervention effects were present on measures of growth, parent-reported internalizing behavior, and teacher-reported work habits.[71] Findings suggest that the early home-visiting intervention attenuated some of the negative effects of early growth faltering, possibly by promoting maternal sensitivity and helping children build strong academic habits that enabled them to benefit

from school.

Intervention Studies

As illustrated by the transactional system,[23] optimal child development depends not only on food quality and availability, but also on the care the family provides to the child, especially during the first few years of life.[76] Evaluations of psychosocial stimulation delivered to undernourished children provide evidence for the importance of caregiving environment in promoting development.[1] In Jamaica, Grantham-McGregor and colleagues[77] demonstrated that stunted children who received either nutritional supplementation or psychosocial stimulation showed improved mental and motor development. The effects of the interventions were additive, children who received *both* supplementation and stimulation achieved mental and motor scores that approximated those of the nonstunted comparison group. Long-term follow-up demonstrated benefits that extended into early adult promoting competence and reductions in violent behavior.[78] These findings demonstrate that the benefits of environmental enrichment are sustainable over time. Recent evidence has shown the benefit of integrating nutrition and early psychosocial stimulation/learning opportunities into intervention trials.[79] In another example of an integrated nutrition and early psychosocial stimulation/learning intervention, zinc supplementation had beneficial effects on general infant development, but only in the context of psychosocial stimulation,[80] suggesting that the beneficial effects of the supplement may only be apparent in the context of a stimulating environment. Thus, more work is necessary to clarify the interactive role between nutrients and the caregiving environment.

MICRONUTRIENTS

Micronutrient deficiencies have been linked to delays in children's development, especially iodine, iron, and zinc deficiencies.[81] Micronutrients represent small quantities of essential vitamins and minerals that promote healthy growth and development. Since they are not produced by the body, they must be acquired either through the diet, fortification, or supplementation. The relationship between micronutrient deficiency and early cognitive development has captured global attention because micronutrients are related to specific physiological and neurological processes.[82]

Fatty Acids

The *n*-3 and *n*-6 polyunsaturated fatty acids (PUFAs) in the human brain are predominantly docosahexaenoic acid (DHA) and arachidonic acid (AA). Both DHA (*n*-3 PUFA) and AA (*n*-6 PUFA) accumulate in neural tissues during gestation and the first year of life. There is evidence from animal studies that DHA in essential to brain structure and function.[83,84] Studies in rats have shown that parental restriction results in reduced brain DHA concentration in the offspring, which is accompanied by poor cognitive and behavioral test performance.[84] The evidence from human studies on the role of DHA has focused largely on maternal depression and child development and behavioral disorders.[84–86] For example, an ecological analysis found an association between low seafood consumption, a key source of *n*-3 PUFAs, and the prevalence of postpartum depression.[85] In addition, maternal seafood intake during pregnancy of less than 340 g per week was associated with increased risk of their children being in the lowest quartile for verbal IQ, compared with mothers who consumed more than 340 g per week. Low maternal seafood intake was also associated with increased risk of poor outcomes for prosocial behavior, fine motor, communication, and social development scores.[86] Although the exact mechanism by which PUFAs, especially DHA, affect development and behavior remains unclear, it is thought that deficits in frontal cortex dopamine neurotransmission seen in patients with attention-deficit hyperactivity disorder (ADHD) may be associated with lower brain DHA concentrations.[84] Children with ADHD have also been shown to have lower plasma or red blood cell DHA concentrations.[87]

Fatty Acid Interventions

Because PUFAs are most actively accreted into the fetal brain during the last trimester of pregnancy, preterm infant are especially vulnerable for PUFA deficiency.[88] Many of the intervention studies have been conducted to investigate the effect of *n*-3 long-chain polyunsaturated fatty acid (LCPUFA) supplementation during the perinatal period on neurobehavioural development of young children.[89] Most of these trials have involved infants from high-income countries, and a significant proportion has investigated supplementation of infant formulas. Generally, supplementation of infant formula for preterm rather than term infants has demonstrated more consistent, positive effects on aspects of neurobehavioral development. The effect of maternal supplementation on global neurobehavioral outcomes for children born at term remains

unclear, although *n*-3 LCPUFA supplementation of women expressing milk for their preterm infants does improve their performance on tests of global neurodevelopment. Further work is required to determine whether dietary *n*-3 LCPUFA is neuroprotective for term infants and for children from disadvantaged or low-income backgrounds.

Iodine Deficiency

Iodine deficiency is a major problem that affects children in areas where iodine is depleted from the soil, primarily mountainous regions, such as the Himalayas and the Andes, and flood plains. Iodine is an essential component of at least two thyroid hormones that are necessary for skeletal growth and neurological development.[90] When iodine is deficient, hypothyroidism occurs, resulting in increased production of thyrotropin, which stimulates production of thyroid hormones. The most common manifestation of iodine deficiency is goiter, which is an enlarged thyroid gland.

When iodine deficiency occurs in utero, it leads to fetal hypothyroidism and irreversible neurological and cognitive deficits, manifested as cretinism. Neurological cretinism includes mental retardation, primitive reflexes, visual problems, facial deformities, stunted growth, and diplegia.[91] When iodine deficiency occurs postnatally, the child may experience thyroid failure that can lead to hypothyroidism. Observational studies that have compared children with and without a goiter have had mixed results; some have reported cognitive deficits among children with goiters and others have not. One explanation for the lack of clarity may be that differing levels of hypothyroidism can lead to a goiter. In addition, families who live in iodine- deficient areas are often more impoverished than families in areas where iodine is adequate.

Iodine Interventions

Several randomized trials have been conducted to examine the impact of iodine supplementation on the cognitive performance of children in iodine-deficient areas. However, results have not been consistent. In a longitudinal follow-up of school-age children, all of whom received iodine, those who received iodine in utero prior to the third trimester had better scores on a measure of psychomotor performance than children who received iodine later in pregnancy or at age 2 years.[92] There was a similar trend when measures of cognitive performance were considered; however, the differences did not reach significance. Thus, the effects of postnatal

iodine deficiency on children's cognitive performance are less clear than the effects of prenatal iodine deficiency.

There has been significant progress in global programs to reduce iodine deficiency, including a decrease in the number of iodine deficient countries (54–30) and an increase in the number of iodine sufficient countries (67–112). However, approximately 30% of households worldwide do not have adequate access to iodized salt, making iodine deficiency and associations with cognitive deficits an ongoing concern.[93]

Iron Deficiency

Iron deficiency (ID) is the most common nutritional deficiency in the world. UNICEF and WHO committees estimate that worldwide there are 2 billion individuals with anemia and up to 5 billion who are iron deficient. The highest risk of ID occurs during times of rapid growth and nutritional demand, during infancy (6–24 months of age), early childhood, adolescence, and pregnancy.[94]

Iron is necessary for hemoglobin synthesis. ID leads to reduced oxygen carrying capacity and can impact immunity, growth, and development. Although iron status is often assessed by anemia (low blood hemoglobin concentration), only 50% of anemia is caused by ID.[92] Iron has multiple roles in neurotransmitter systems and may affect behavior through its effects on dopamine metabolism.[95] This is highly relevant to children's cognitive development as dopamine clearance has strong effects on attention, perception, memory, motivation, and motor control.[96]

Approximately 47% of the world's children under age 3 have anemia,[94] with higher rates in low-income countries. ID is the most common cause of anemia and has been associated with multiple adverse health conditions, including low scores on tests of mental performance and were fearful, inattentive, and solemn with low levels of initiation and exploration, and many continued to demonstrate lower academic performance during their school-age years, even when the anemia had been treated.[97] For example, a follow-up of Costa Rican adolescents who had been born at term and were free of health problems in infancy other than ID, showed persisting motor differences, more grade repetition, increased anxiety/depression, social problems and inattention rated by parents and teachers, and a widening gap in cognitive scores to 19 years, despite iron therapy that corrected Iron-deficiency anemia (IDA) in infancy.[98]

Iron Interventions

Prevention of iron deficiency is a primary public health goal in many counties. However, evidence from prevention trials has been mixed. Several recent reviews of randomized controlled trials of iron supplementation provide evidence for improved motor and social-emotional development in infants who received iron.[99–101] However, other reviews have suggested that although supplementation trials reduce anemia, the effects on development are inconsistent and uncertain.[97] The variability in the quality of the trials, including the timing, dose, and duration of the supplement, make comparisons across studies.

Zinc Deficiency

Zinc is a trace mineral that is involved with DNA and RNA synthesis and the metabolism of proteins, carbohydrates, and fat. There have been at least 15 trials of the association between zinc supplementation and cognitive performance among infants and young children. Although zinc is essential for neurological functioning and observational studies have shown associations between low zinc concentration and negative performance and mental health status, randomized trials of zinc alone or in combination with other micronutrients have yielded inconsistent results linking supplementation with children's early development.[102] Many factors could interfere with clear interpretation of the zinc supplementation trials. Zinc deficiency is difficult to document, interfering with the ability to ensure that participants are zinc deficient. Micronutrient deficiencies often co-occur, thus providing zinc alone or with iron may not alleviate other nutritional problems. There may be interactive effects between zinc and iron, resulting in adverse effects. Nutritionally deficient infants, who are smaller, less active, and less competent than better nourished infants, may be less able to elicit age-appropriate expectations from their caregivers. It is also possible that the intervention trials were too brief or the dose of zinc supplement was insufficient. Finally, the low-income context surrounding zinc deficiency may interfere with children's developmental progress, even in the context of zinc supplementation.

Multiple Micronutrients

Infants in low-income populations are at risk for multiple micronutrient deficiencies due to inadequate dietary intakes, poor bioavailability in foods, and delayed introduction of complementary foods. Thus supplementation of multiple micronutrients from 6 months through early

childhood has been proposed as a strategy to prevent multiple deficiencies and promote brain development. While several studies have assessed the effects of iron and zinc supplementation on infant development, findings have been inconsistent. In Bangladesh beneficial effects of the two micronutrients were reported on infants' motor development and behavior.[103] However, in Indonesia, infants showed benefits on psychomotor development from iron but not zinc or iron plus zinc supplementation.[104] In Zanzibar, infants aged 5–11 months given either iron plus folic acid or iron plus folic acid plus zinc walked unassisted sooner than did those who received zinc alone or a placebo.[105] Conversely, iron plus folic acid and zinc supplementation, alone or in combination, did not affect the age at first walking unassisted in Nepal.[106] Overall, these studies suggest a possible benefit of iron supplementation, but are inconsistent as to the effects of multiple micronutrients on infant development.

The long-term effects of multiple micronutrient supplementation on child development remains unclear. While one study reported that intellectual function of school-aged Nepalese children was positively associated with prenatal iron plus folic acid supplementation,[107] at least three other longitudinal randomized controlled intervention trials have reported no long-term developmental benefits of multiple micronutrient supplementation during infancy, toddlerhood, or the preschool period. In rural Nepal, zinc and iron plus folic acid supplementation during infancy (4–17 months of age) did not improve motor and language milestone scores of toddlers,[108] and iron plus folic acid during the preschool years (12–35 months of age) had no effect on aspects of intellectual, executive, and motor function at 7 to 9 years of age.[109] In Thailand, supplementation with iron or zinc or both during infancy did not lead to long-term cognitive improvement in 9-year-old children.[110] There is little evidence to suggest routine prophylactic multiple micronutrient supplementation of children in low-income populations at high risk for deficiencies improves developmental outcomes. Further studies are needed to evaluate the effect of timing, type, and duration of single and multiple micronutrient supplementation on developmental outcomes.

NEUROTOXINS

Lead Exposure

Numerous studies have documented that lead exposure has a neurotoxic

effect on infants and young children and is associated with impairments in intellectual and behavioral functioning.[111,112] Although significant progress has been made in reducing the average blood lead level in many parts of the world, lead remains a major cause of encephalopathy in children. Even in the absence of encephalopathy, lead poisoning contributes to permanent neuropsychological impairments including deficits in general intellectual functioning, ability to sustain attention on tasks, aspects of speech production and language comprehension, motor coordination, flexible problem solving, and behavioral self-regulation. Several recent reviews that focused on the impact of low levels of lead exposure (blood lead levels < 10 μg/dL) among children indicated that even low-level lead exposure can lead to a decline in IQ scores.[113,114] An international pooled analysis found a dose–response effect associated with the amount of lead found in children's blood.[114] An increase in blood lead levels from 2.4 μg/dL to 10 μg/dL resulted in a 1.1 point decline in IQ, 10 μg/dL to 20 μg/dL resulted in an additional 1.9 point decline, and for blood lead concentrations from 20 μg/dL to 30 μg/dL there was an additional 3.9 point decline in IQ scores (a total decrement of 6.9 IQ points for the 20–30 μg/dL group).

In general, the long-term effects of prenatal or postnatal lead exposure appear to be nonspecific, impacting multiple areas of the brain and making it difficult to pinpoint the specific neurodevelopmental mechanisms responsible for cognitive and behavioral changes in lead-exposed children. However, there is evidence that lead alters neuropsychological development by disrupting processes of neuronal migration, synaptogenesis, and myelination.[115] Many of the neurotoxic effects of lead can be traced to lead's ability to mimic or inhibit the action of calcium as a regulator of cell function. As such, exposure to lead causes changes in how neurotransmitters are stored and released, which may cause an inhibition of synaptic growth and detract from the efficiency of the developing brain. Lead also disrupts the main structural components of the blood–brain barrier by damaging astrocytes and the endothelial microvasculature. This damage allows for the passage of certain molecules (e.g., albumin) that are toxic and typically restricted by the blood–brain barrier.[116] Other researchers note that lead exposure alters second and third messenger activity,[117] which also interferes with cognitive efficiency.

Children are typically more vulnerable to lead exposure than adults because they are more likely to ingest lead, resulting in severe consequences. Hand to mouth activity and behaviors such as pica (which

peaks at around 2 years of age) increase the likelihood of ingesting lead-contaminated substances.[113] The most common ways that children are exposed to lead are through the consumption of soil, lead-based paint, water from pipes with lead-soldered joints, and contaminants brought home from parents engaged in mining/industrial activities. Once ingested, lead may have a more deleterious effect on the developing central nervous system of children than on adults. Children's increased vulnerability to lead is attributable to several factors. First, a greater proportion of ingested lead is absorbed from the gastrointestinal tract of children than of adults. Second, a greater proportion of circulating lead crosses the blood–brain barrier in children, especially children under the age of five, than in adults.[115] Finally, the developing brain seems to be more vulnerable to the neurotoxic effects of lead than the mature brain. The neurotoxic effects of lead are particularly evident in the prefrontal cortex, the cerebellum, and the hippocampus.[117] Investigators speculate that because regions such as the prefrontal cortex are in a phase of rapid development during the first few years of life, they may be particularly susceptible to the harmful effects of neurotoxins. The vulnerability of the prefrontal cortex could also explain the consistent associations between elevated blood lead levels and poor performance on tasks involving sustained attention and other executive functioning.

SUMMARY

Most of the research examining the impact of nutritional deficiencies on children's intellectual development has hypothesized a direct effect, possibly through changes in neuroanatomy or neurotransmission. However, evidence from both animal and human studies has shown that children's development is influenced by environmental factors, especially the quality of interactions with primary caregivers. Thus, behavioral changes associated with nutritional deficiencies may alter the caregiving that the child receives, thereby compromising the child's development even further. The result could be a child who experiences both the neurochemical changes that have been associated with nutritional deficiency, together with limited environmental enrichment. Initial findings from integrated trials that include both nutritional supplementation and early learning/stimulation opportunities have been promising. Future research should consider whether the caregiving system mediates the effects of nutritional deficiencies on child development, and how integrated interventions that include nutrition and early

learning/stimulation relate to child development.

Observational studies have consistently shown associations between single nutrient deficiencies and children's intellectual development. Yet, evidence from intervention trials of single nutrients has been inconsistent. In many low and middle-income countries, children experience deficiencies in multiple nutrients, often in the context of poverty. Trials are needed that correct both macro and micronutrient deficiencies, and provide opportunities for responsive learning/stimulation often lacking in low-income contexts.

The findings linking nutritional deficiencies and child development point to the importance of effective prevention programs that begin prenatally or early in life and extend through the periods of vulnerability, which may include adolescence. There are many unanswered questions regarding nutritional deficiencies and child development that require further research to guide prevention, including the timing of interventions to prevent deficiencies, the specific processes involved in effective prevention, and the long-term benefits on academic achievement and human capital.

Maternal Nutrition and Pregnancy Outcome

25

Theresa O. Scholl, PhD, MPH and Xinhua Chen, MD

Poor maternal nutrition is associated with an increased risk of serious complications and adverse outcomes during pregnancy. However, in humans, poor nutrition is often coupled with poverty and disadvantage, inadequate prenatal care, smoking, and drinking, making its effects difficult to disentangle.

In the classic study of a rare event, a World War II famine where there was a serious food shortage in a previously well-nourished population, it was noted that pregnant women lost weight, the birth rate declined, infant mortality increased, and the rate of infant low birth weight increased. When the peak of famine occurred during the first trimester, there was an excess of preterm births and an increase in infants weighing <2000g.[1] In addition to reducing the total amount of food that was eaten, famine would also have reduced many micronutrients and nutrients important to maternal–fetal being iron, folate, and calcium among others. Current recommendations for nutrient intakes that are important for pregnant women, along with information about the upper limit considered safe, are given in Appendix B.

Long-term consequences of poor maternal nutrition and other factors are discussed in Chapter 27. But, one of the immediate consequences of the famine would have been an increase in maternal anemia. Anemia, measured by low hemoglobin or hematocrit, is the most prevalent

nutritional deficiency in the world affecting 40% of pregnant women.[2] By Centers for Disease Control and Prevention estimates, anemia increases from 7.6 % in the first trimester to 33.9% during the third trimester.[3] The etiology of anemia is multifactorial, including hemoglobiopathies, acute infections, chronic inflammation, and diets poor in nutrients such as folate, vitamin B12, and vitamin A, along with iron, the most commonly recognized nutritional cause.

IRON, IRON DEFICIENCY, AND ANEMIA

During pregnancy, the maternal body requirement for iron increases to approximately 1000 mg.[4] Of this 350 mg is associated with fetal and placental growth, 500 mg with expansion in the red blood cell mass, and 250 mg with blood loss at delivery. The increased iron requirement needs to be supported by higher maternal iron intake - increasing from 6 mg/d in the first trimester, to 19 mg/d in the second trimester, to 22 mg/d in the third trimester.[4] To meet these increased requirements, gravidae must draw upon stores, thus increasing the risk of iron deficiency and iron-deficiency anemia (IDA).

Iron deficiency and anemia are prevalent among women who are pregnant or in their reproductive years usually because of a low intake of absorbable iron. Data from National Health and Nutrition Examination Survey (NHANES) III show a median iron intake of 14.7 mg/d of for pregnant women, with approximately 90% below the estimated average requirement for pregnancy (22 mg/d).[5] In addition to a poor-quality diet, poor iron absorption and blood loss—from menstruation, during labor and delivery, or from rapid repeat pregnancy—are other important causes of iron deficiency in women.[4] Among reproductive age US women who are not pregnant, IDA estimated from low hemoglobin and two of three iron indices was present in 2%–5%, while iron deficiency occurred in 11%–16%.[5]

Iron deficiency is defined by three stages of increasing severity: depletion of iron stores (stage 1), iron deficiency without anemia (stage 2), and IDA (stage 3). Low hemoglobin and hematocrit assess anemia in general but not specifically iron deficiency or IDA. Due to hemodilution during pregnancy, the optimal time to study effects may be before pregnancy or early in gestation before the plasma volume is fully expanded. This was originally examined in Camden by separating anemia by time (early vs. later gestation) and etiology (IDA and anemia from

other causes). IDA detected early in pregnancy was related to inadequate gestational weight gain from a diet deficient in energy and iron and resulted in a greater than twofold increase in the risks of low birth weight and preterm delivery, whereas anemia from other causes was unrelated to increased risk. In the third trimester, preterm delivery was less frequent for women with IDA.[6,7] Similar results were reported from Chinese workers tested for anemia before they became pregnant; 83% were anemic; but only 8% had IDA.[8] Pregravid anemia was associated with lower birth weight (−100 to −125 g), whereas IDA was associated with a birth weight deficit of −240 g.[8] Likewise, anemia detected early in pregnancy—during the first or second trimester—is usually associated with a higher risk of preterm delivery and low birth weight,[9,10] whereas anemia during the third trimester generally is related to a decreased risk of these adverse outcomes.[9]

Plausible mechanisms underlying the effect of anemia in pregnancy include (1) chronic hypoxia from anemia that initiates a stress response; (2) increased oxidative stress that damages the maternal–fetal unit; and (3) reduced maternal immune function with increased infection leading to preterm delivery and reduced fetal growth.[11]

While anemia is a risk factor, clinical trials that involve supplementation with iron or iron/folic acid have been equivocal. A recent Cochrane review found that women receiving iron or iron/folic acid supplements had infants significantly heavier (+58 g) than women on placebo or other regimens with no difference in preterm delivery, small-for-gestational-age (SGA) infant, or low birth weight.[12] A more recent meta-analysis also found difference in low birth weight (25% reduction)[13] after including a recent trial from rural China where iron/folic acid supplements increased gestation duration (+0.23 weeks) and reduced risk of very preterm delivery <34 weeks (0.98% vs. 1.8%).[14] Thus, supplementation may more effectively reduce the risk of adverse outcomes when the proportion of women who are iron deficient or anemic is high.[15] It is also plausible that duration is an issue. Supplements may need to be started early in pregnancy if not beforehand and continued throughout the reproductive years to reduce risk.[12,15]

Although clinical trials have shown almost uniformly that iron supplementation results in a reduction in anemia, they have raised the possibility that giving too much iron to nonanemic women, that is, daily administration of ≥50–60 mg/d, can increase blood viscosity and associated poor outcomes.[12,15] Thus, selective supplementation of women

with poor iron stores may be preferable to routine supplementation. Iron is potentially toxic and could expose women who are not deficient to high levels of oxidative stress and has no benefit for mother or fetus.[11,15] High maternal hemoglobin has consistently been associated with failure of the plasma volume to expand and adverse outcomes related to maternal pathology—gestational hypertension, preeclampsia, and diabetes.[12] Increased levels of the iron storage, ferritin, also are associated with preterm delivery but likely via chronic inflammatory changes.[16] Thus, the relationship between maternal hemoglobin and pregnancy outcome is said to be U shaped with low hemoglobin reflecting a mix of true and physiologic anemia and high hemoglobin reflecting failure of the plasma volume to expand or hemoconcentration related to an iron excess.

FOLIC ACID

Folic acid is a water-soluble B vitamin (B9) present in leafy green vegetables, dried beans, and fruits that is used to fortify flour and cereals in the United States. Humans cannot synthesize folate and are entirely dependent on dietary sources or folic acid supplements for their supply. Folate is important for the production of S-adenosyl methionine, a universal donor of methyl groups that transfers one-carbon units to be used for DNA methylation. Folate is required for cell division because of its role in DNA synthesis and is a substrate for reactions that affect metabolism of amino acids on the transmethylation and transsulfuration pathways.

A central feature of fetal development is widespread and sustained cell division. Because of its role in nucleic acid synthesis, the need for folate increases during times of rapid tissue growth. During pregnancy, folate-dependent processes include increase in the red blood cell mass, enlargement of the uterus, and growth of the placenta and fetus along with epigenetic regulation of differentially methylated regions (DMRs) of the fetal genome. During the aforementioned Dutch Famine when periconceptional exposure to the famine occurred, there was an increase in the frequency of malformations of the central nervous system, including spina bifida,1 which is consistent with a deficiency in folate and other methyl donors. A long-term effect was noted six decades later in the lower methylation status of the *IGF2* gene with fetal exposure to famine during early gestation.[17] The *IGF2* gene is maternally imprinted and produces insulin-like growth factor 2 that is important for growth and development. In the case of *IGF2*, the imprinted allele from the mother normally is

silenced and only the father's nonimprinted allele is expressed. Lower methylation of the IGF2 DMR would be expected to lead to increased expression of both maternal and paternal IGF2 alleles.[17]

It is recommended that reproductive age women consume 400 μg folic acid from supplements or fortified foods, in addition to folate-containing foods from their diet, to reduce the risk of neural tube defects, increasing to 600 μg/d during pregnancy (see Appendix B). Approximately one-third of women in their reproductive years consume the recommended amount.[18] Fortification of flour and cereal products in the United States with folic acid (since 1998) has been associated with a 19% decline in the risk of live born infants with neural tube defects, along with a 27% decline in anemia in women along with increases in hemoglobin, hematocrit, serum folate, and a decline in homocysteine levels.[19,20]

Although these are positive changes, maternal periconceptional supplementation with folic acid may also have led to epigenetic modifications and changed expression of some fetal genes. In one study, maternal periconceptional use of ≥400 μg folic acid/d was linked to increased methylation of IGF2 DMRs among infants[21]; the findings that are opposite to the Dutch Famine. In another study, maternal use of folic acid supplements before and during pregnancy was associated with increased methylation of H19 DMR but not IGF2 DMR in cord blood.[22] The long-term consequences of these epigenetic changes, if any, are not known. Current knowledge about early intrauterine exposures, epigenetics, gene expression, and their sequelae are reviewed in Chapters 19 and 20.

Serum folate is a sensitive indicator of the folate available to replicating cells with high turnover rates, whereas red blood cell folate reflects folate status over preceding months. A metabolic effect of a deficiency in folate (B_9) and other B vitamins (B_6 and B_{12}) is an elevation of homocysteine.[23] Hyperhomocysteinemia, a risk factor for cardiovascular disease, is a known cause of vascular damage and endothelial dysfunction. If homocysteine was related to poor placental development or attachment, then high levels might do injury in the course of pregnancy, increasing serious complications like placental abruption and preeclampsia where endothelial damage is a significant factor. The consequences for pregnancy would be expected to reflect placental vascular compromise, that is, reduced infant birth weight and increased rates of fetal growth restriction and preterm delivery.[23–25]

Homocysteine, when measured in more than 5800 Norwegian women aged 40–42 years, was positively related to a past reproductive history that

included preeclampsia, preterm delivery, low birth weight, and fetal growth restriction.[26] High homocysteine, examined in Chinese workers before conception, was associated with a fourfold increased risk of preterm delivery, not SGA.[27] A longitudinal study, with repeated measurement of maternal homocysteine from before conception, reported lower weight infants (~200 g) born to mothers with higher homocysteine; whether this was attributable to shorter gestation duration is unclear.[28] More recently, investigators from the Generation R study, which assayed both homocysteine and folate early in pregnancy (13 weeks gestation on average) reported that low folate and high homocysteine were each related to lower placental weight (~−26 to −30 g) and infant birth weight (−110g to −125 g). Twofold increases in risks of preterm delivery and preeclampsia were evidenced with low folate (lowest quintile) but not high homocysteine (highest quintile); SGA risk was increased twofold with each. When both folate (low) and homocysteine (high) were examined jointly, there was a fourfold increased risk for SGA and preeclampsia.[25] That low folate was more regularly associated with increased placental vascular resistance during mid to late gestation than homocysteine, suggesting a direct effect of folate on the placental vasculature with homocysteine being a response to or marker for poor folate status.[25]

Inadequate intake of folate leads to impaired cell division and alterations in protein synthesis. An absolute deficiency of folate—from a diet inadequate to meet the needs of pregnancy—will interfere with growth of the fetus and duration of gestation.[23] We have shown in the Camden study that low dietary and circulating folate, measured early in gestation, tripled the risk of low-birth-weight infant and preterm delivery and interacted with a deletion allele for a folate-metabolizing gene enzyme (dihydrofolate reductase [DHFR]) that converts folic acid that is used in supplements and to fortify the US food supply to the reduced folate forms used by cells. Presence of the DHFR deletion allele increased the risk of preterm delivery threefold, and low intake of folate increased the risk of low birth weight eightfold and risk of preterm birth fivefold.[29,30] Lower folate intake (<500 μg/d) at mid-gestation was associated with approximately twofold increased risk of preterm delivery in women from North Carolina as were low levels of serum and red blood cell folate[31] and the folate metabolite 5 methyltetrafolate.[32] Others have reported increased infant birth weight for mothers whose folate intake was high and positive correlations between maternal serum and red cell folate with birth weight or gestation duration.[33]

In particular, effects of folic acid supplementation before and during the course of pregnancy are unclear. A large cohort of women who supplemented for at least 1 year with folic acid had a 70% reduction in risk of delivering before week 28 and a 50% reduction for delivery between 28 and 32 weeks.[34] After folic acid fortification of the US food supply, rates of preterm delivery, very low birth weight, and low birth weight declined between 4% and 10% among Californian liveborn infants[35] and elsewhere.[36] A recent meta-analysis found an overall effect of folic acid on birth weight corresponding to a 2% increase for each doubling of the folic acid supplement.[37] While smaller scale trials have and have not reported reductions in risk,[33] a large randomized study found no effect of folic acid supplements on mean birth weight, gestation at delivery, or placental weight.[38] After pooling with data from another trial, a high dose of folic acid (5 mg/d) was associated with a 37% reduction in risk of low-birth-weight infant.[38] Likewise, although supplementation with folic acid (with/without iron) showed no effects on the white South African women, the risk of bearing an infant of less than 1870 g was reduced fourfold among the Bantu participants, who subsisted primarily on maize porridge.[39]

In summary, although observational studies of folate and pregnancy suggest a potential benefit of folate supplementation during pregnancy—a decrease in serious complications and an improvement in birth weight and gestation—randomized trials imply that women who are at risk, either because of common genetic polymorphisms that alter folate metabolism or because of environmental factors associated with a diet low in folate, would seem to benefit the most. Many of the investigators who did not find lower folate (circulating levels, diet, or supplements) to be related to preterm delivery or gestation duration did not confirm the mother's last menstrual period (LMP) by ultrasound with resulting misclassification and loss of precision to detect an effect.[32]

While supplementation with folic acid before pregnancy carries an enormous benefit—a reduction in risk of neural tube and other congenital defects—it may also alter the methylation patterns in DMR for some fetal genes. It is now an open question whether supplementation with folic acid before and during gestation will have consequences for the exposed fetus as it grows and develops.

CALCIUM

The skeleton acts as the calcium reservoir of the body (99% is stored there), and when dietary calcium intake is low or poorly absorbed, calcium is withdrawn from the bone to support serum calcium homeostasis.[40] During pregnancy, retention of an estimated 30 g of calcium, most of which is transferred during the third trimester, is needed to mineralize the fetal skeleton.[40] Although it is often assumed that pregnancy, like lactation, might be a setting for bone mass loss because of this requirement, this might be buffered by a 60%–70% enhancement in intestinal calcium absorption during pregnancy which is mediated by 1,25 dihydroxyvitamin D, the active form of vitamin D and other calcitropic hormones. This view is supported by cross-sectional studies of bone mass and parity, usually confined to mature white women, which show increased bone mass and decreased fracture risk or no effect of parity on bone mass.[41]

The few available longitudinal studies have come to a different conclusion, they suggest that trabecular bone, which has a larger surface area, is softer than cortical bone, and more readily mobilized may be another source of the calcium needed to ossify the fetal skeleton.[41] Longitudinal research on change in bone mass with pregnancy usually report small gains in cortical bone but significant decreases in sites (spine and pelvis) where trabecular bone predominates.[41,42] One reason for the limited research is risk of radiation exposure. Measurement of the mother's appendicular skeleton by other means—ultrasound or peripheral quantitative computed tomography—also shows decreases in bone at some sites. One study reported a quantitative ultrasonographic index 3.6% lower at six weeks postpartum compared to early pregnancy.[43] In another, measurements of the distal radius on the nondominant arm showed no loss in cortical bone but a 1.6% decrease in trabecular bone density between first and third trimesters compared to nonpregnant controls.[44] Although the amount of bone lost is typically small, it is consistent with the fetal demand for calcium.

Low calcium intake, which is an important determinant of bone mineralization, could also influence bone changes. Higher calcium intakes during childhood and adolescence are associated with higher bone mass at maturity.[45] If dietary calcium intake is very low (<500 mg/d), then decreases in serum calcium and calcium absorption would be expected.[41] Lower serum calcium increases parathyroid hormone (PTH) that stimulates production of 1,25(OH)2D, the active form of vitamin D. Increased production of $1,25(OH)_2D$ enhances calcium absorption from

the gut, mobilizes skeletal calcium, and reduces urinary calcium excretion to maintain calcium balance. When calcium intake is chronically low and calcium is added to the maternal diet, positive changes in bone mineral density have been noted as well as reduction in markers of bone turnover.[41]

During adolescence, the bone mineral content of the femur and the lumbar spine increase by 50%–150% and volumetric bone mineral density increases by 10%–30%.[46] Factors that interfere with normal accrual may be related to later osteoporosis,[47] and regions that are actively growing may be more severely affected.[46,47] During adolescent pregnancy, calcium nutriture could be limited by maternal diet but simultaneously driven by the need to retain enough calcium to mineralize two skeletons. Approximately 50% of teenagers continue to grow while pregnant.[48] Ultrasonographic bone measures of the os calcis showed that bone loss was greater for growing teenage gravidae (−5.5%) than for mature women (−1.9%).[43] Iowa women with an adolescent pregnancy (<19 years) had, at maturity, a bone mass at the mid distal forearm that was below controls.[49] Calcium consumption was also related to bone and the joint effect of an early pregnancy, and lower calcium intake was substantial.[49] This is consistent with a recent study which suggested that an adolescent pregnancy resulted in a twofold increase in the risk of osteoporosis and a tendency to more osteoporotic fractures in postmenopausal Korean woman.[47]

Diets low in calcium, especially during pregnancy, are associated with increased blood pressure levels through heightened smooth muscle reactivity (see Appendix B for recommended dietary intake of calcium and other nutrients during pregnancy). Belizan and Villar[50] reported an inverse relationship between eclampsia and dietary calcium from ecologic-level data that showed countries where calcium intake was low had a higher frequency of eclampsia than countries where calcium intake was higher.

A meta-analysis of 14 randomized, controlled trials of calcium supplementation involving more than 2400 pregnant women showed statistically significant reductions in systolic and diastolic blood pressure with the administration of calcium salts (375–2000 mg/d elemental calcium).[51] Risk of preeclampsia was reduced more than twofold among women supplemented with calcium during these trials. Duration of treatment ranged from 10 to 22 weeks, with most studies starting the supplement during the second trimester. Although differences in the risk of preeclampsia were significant in the aggregate, only two of the nine

studies showed statistically significant differences.

A large, randomized, double-blind, placebo-controlled trial of 5489 low-risk nulliparous women showed no effect of calcium supplementation.[52] Pregnant women were enrolled at centers throughout the United States, supplemented with 2 g of elemental calcium (or placebo) beginning at 13–21 weeks gestation and continuing until they delivered. Calcium supplementation did not significantly reduce the risk of preeclampsia, gestational hypertension without preeclampsia (either mild or severe), or pregnancy-associated proteinuria without hypertension. Blood pressure was also unaffected; however, participants' dietary intake of calcium was high, averaging about 1100 mg/d.[52]

It seemed likely that an effect of calcium on preeclampsia might be confined to high-risk populations in which there was either a severe dietary restriction of calcium or a high demand for calcium as in adolescent pregnancy. The World Health Organization (WHO) trial that involved more than 8300 pregnant women from populations where dietary calcium intakes were low (<600 mg/d) supported the original ecologic observations made on eclampsia.[53] Calcium supplements (1.5 g/d) did indeed reduce the relative risk of eclampsia (by 47%), severe gestational hypertension (by 40%), severe preeclamptic complications (by 32%), the severe maternal morbidity and mortality index (by 25%), and neonatal mortality (by 43%). The overall risk of preeclampsia was not lower on the calcium regimen than placebo (4.1% vs. 4.5%). However, a meta-analysis pooling data from clinical trials that randomized more than 15,000 women concluded that calcium supplementation did in fact reduce the overall risk of preeclampsia (Relative Risk (RR) = 0.45, 95% confidence interval [CI] 0.31–0.65) and by 65%–75% for women at high risk for preeclampsia (RR = 0.22, 95% CI 0.12–0.42) or with low calcium intake (RR = 0.36, 95% CI 0.20–0.65).[54]

During pregnancy, an increased risk of gestational hypertension or preeclampsia associated with lower calcium intake could result in an increased risk of an indicated preterm delivery. Consequently, supplementation with calcium during pregnancy could have a side effect of reducing preterm birth. The WHO trial showed that for women aged 20 years or younger, very preterm delivery (<32 weeks) was significantly reduced (by 56%) and preterm delivery showed a nonsignificant trend in the same direction.[53] The aforementioned clinical trial performed by Levine et al. found no effect of calcium supplementation on obstetric outcomes, including preterm delivery, birth weight, low birth weight, or

fetal growth restriction.[52] A meta-analysis of trials that randomized more than 15,000 women found that calcium reduced the risk of preterm delivery by ~30% (RR = 0.76, 95% CI 0.60–0.97) and by 50% in 4 trials (*N* = 568) where women were at high risk for preeclampsia (RR = 0.45, 95% CI 0.24–0.83).[54]

VITAMIN D

Vitamin D, a collection of fat-soluble secosterols, is present in few foods naturally (fatty fish, fish liver oils), used for food fortification (fortified milk, breakfast cereals, orange juice), and included in nutritional supplements (prenatal multivitamins). It is also synthesized photochemically by the skin after exposure to ultraviolet B (UVB) radiation from the sun. The circulating level of 25(OH)D is the best indicator of vitamin D status representing the amount of vitamin D produced cutaneously and ingested from diet and supplements.[40] Prevalence of vitamin D deficiency and insufficiency is modified by skin pigmentation. More pigment-intense skin will block UVB absorption and increase the risk of poor vitamin D status so that the risk of vitamin D deficiency and insufficiency is higher among African Americans and intermediate among Hispanics compared to whites.[40]

$1,25(OH)_2$ vitamin D is the active form of the vitamin related to calcium and homeostasis, bone health, and other physiologic functions.[40] Several recent studies found an increased risk of preeclampsia with maternal 25(OH)D consistent with insufficiency deficiency as well as with low intake of total vitamin D although others have not.[55] Two prospective studies, one of them longitudinal, reported lower serum 25(OH)D in gravidae who subsequently developed preeclampsia[56,57] as well as in their infants.[56] However, they disagreed on when risk was detectable, either early in gestation (10 weeks on average) or later (weeks 24–26) without an earlier window.

Neither the National Institutes of Health (NIH)[52] nor the WHO trial[53] of calcium and preeclampsia measured 25(OH)D. Many of the participants from the WHO trial were from the tropics, likely exposed to more sunshine with a lower expected prevalence of vitamin D insufficiency than the North American women studied by the NIH. There is an interaction between vitamin D and calcium such that when vitamin D is deficient or insufficient, even high calcium intakes may be inadequate to maintain calcium metabolism.[58] Thus, it is plausible that an effect might have been

detected had the supplement combined calcium with vitamin D.

Overweight and obesity increase the risk of type 2 diabetes and preeclampsia as well as poor vitamin D status. Vitamin D is a fat-soluble vitamin.[40] Adiposity measures, such as skinfolds, body mass index (BMI), total body fat, all correlate inversely with 25(OH)D, and it is likely that there is an increased storage of vitamin D in adipose tissue with consequent reductions in bioavailability.[40] Poor vitamin D status likely alters the insulin response to a glucose load, is associated with increased insulin resistance, and amplifies the systemic inflammatory response characteristic of type 2 diabetes.[40] After adjustment for BMI and other factors, lower circulating levels of 25(OH)D has been implicated in type 2 diabetes.[40] Observational data suggest that circulating levels of 25(OH)D were significantly lower in gestational diabetics compared to normoglycemic women; overall risk of gestational diabetes was increased by 50% with 25(OH)D in the deficient or insufficient range.[59]

In observational studies, Canadian gravidae who restricted drinking milk had infants with lower weights at birth (~80 g); both milk consumption and vitamin D intake were significant birth weight predictors.[60] Vitamin D deficiency is characterized by elevations in PTH. A small study (N = 30) of vitamin D-deficient Pakistani gravidae showed an inverse correlation (r = −0.39, $P < 0.05$) between lower birth weight and higher maternal PTH.[61] Data from Camden also suggested that total intake of vitamin D (diet plus supplements) was a significant predictor of infant birth weight for gestation; the difference in birth weight between the lowest quintile and the highest quintiles of vitamin D amounted to 65 g.[62]

More than two decades ago, it was reported that vitamin D-supplemented Asian women residing in India or living in London gained significantly more weight and had infants with higher weights at birth. The increases ranged from 80 to 410 g birth weight; one study showed a twofold reduction in low birth weight.[63] However, a trial conducted among French women did not show positive effects of vitamin D supplements on birth weight.[63] The overall effect of supplementation was consistent with no change in infant birth weight but a trend toward lower risk of low-birth-weight infant (RR = 0.48, 95% CI 0.23–1.01).[63] Most studies have found no association between vitamin D supplementation and gestation duration or preterm birth[55] with one exception. Australian gravidae with very low levels of 25(OH)D (<28 nmol/L) had gestations that were 0.7 week (4.9 days) shorter than women with higher circulating levels; birth weight was also reduced but the difference (–157 g) was not statistically significant.[64]

Mode of delivery may differ for vitamin D-deficient women. Vitamin D is related to muscle mass and strength.[40] Two studies now suggest an increased risk for cesarean delivery in vitamin D-deficient women.[65,66] When specific indications were examined, vitamin D deficiency was linked to a 2-fold increased risk of Cesarean for prolonged labor in Camden gravidae.[66] Thus, it is plausible that poor maternal vitamin D status increases the risk of Cesarean delivery by reducing pelvic muscle strength and control leading a reduced ability to push and to a longer and more difficult labor.

MULTIVITAMIN AND MINERAL SUPPLEMENTS

In the United States, the use of vitamin and mineral supplements has been increasing, and currently, more than 40% of US women use multivitamins/mineral supplements; 34% of women in their reproductive years regularly take one or more supplements that contain folic acid.[18,67]Appendix B contains information on recommended dietary intakes for pregnant women in the United States including the upper limit that is presumed to be safe.

Multivitamin/mineral supplements contain at least three vitamins and may or may not contain minerals.[67] Although the value individual micronutrients like folic acid and iron have been long recognized, the import of others (vitamin D) has only recently become apparent. Deficiencies of more than one micronutrient are found within as well as between populations depending upon dietary intake, supplement use, food preferences, income, and residence. In poor urban areas in the United States, there are neighborhoods where fresh fruits and vegetables are hard to find and thus rarely eaten. For other nutrients, like vitamin D, there can be wide seasonal variation because of their dependence on seasonal UVB radiation from the sun.

In the developing world, pregnant women are often deficient in a variety of vitamins and minerals, and iron or iron/folic acid supplements alone are less likely to be effective. In one of the first studies, Fawzi et al. examined the effect of supplementing more than 1000 HIV-positive women from Tanzania with multivitamins, vitamin A, and placebo.[68] Multivitamin supplementation decreased the risk of very preterm delivery (approximately twofold reduction) along with risk of low-birth-weight infant and fetal growth restriction. The multivitamin supplement had the bonus of increasing CD4, CD8, and CD3 counts in the women.

Meta-analyses compared outcomes of pregnant women from the developing world presumed to be HIV negative who participated in trials where similar protocols were used. Women were supplemented with multiple micronutrients (usually 1 Recommended Dietary Allowance (RDA)) and controls with iron, iron/folic acid, iron/folic acid/vitamin A, or placebo. Multiple micronutrients reduced low birth weight and SGA by approximately 10%.[69,70] In one of the analyses, multiple micronutrients significantly increased birth weight (+22 g), but depending on the mothers BMI.[69] In gravidae where BMI was <20, there was no effect of the supplement on birth weight; when BMI was 20 or more, birth weight increased by +39 g.[69] There was no effect on gestation duration or on preterm birth; however, gestation was usually based on the mother's LMP, often resulting in implausible combinations of birth weight and gestation,[69] which implies substantial misclassification. Use of prenatal vitamins by women from North America and Europe before and during pregnancy is associated with reductions in the risk of preterm delivery, low-birth-weight infant, and SGA.[71,72]

HERBAL PRODUCTS

Use of herbs or herbal products during pregnancy is increasing worldwide and in English-speaking counties ranges from 7% to 56%.[73–75] Data from the US National Birth Defects Prevention Study showed that 10.9% of women (N = 4239 with nonmalformed infants) used herbals before and during pregnancy amounting to 395,000 US births per year.[74] Actual use is probably higher than the published literature; this may be because of failure to admit use to health care providers or to participate in surveys.

Common herbs along with the indication for their use are listed in Table 25-1.[73–75] Herbal products are used for a wide range of maternal complaints particularly morning sickness, anemia, and infection. Most herbal products are perceived as natural, with benign effects and as safe for use during pregnancy; this may or may not be true.[76] Ginger, which is commonly used for morning sickness and other conditions, has multiple therapeutic properties including antioxidant, antimicrobial, and anti-inflammatory actions.[77,78] Apart from pregnancy, ginger may prevent the development of cardiovascular diseases or cancer.[78] A retrospective study reported that taking ginger and the iron-rich herb echinacea was associated with high-birth-weight infant (3663 g vs. 3508 g, $P < 0.001$).[73] A large study with 68,522 Norwegian mothers suggested that ginger was not

associated with an increased risk of adverse perinatal outcomes including congenital malformation, preterm birth, low birth weight, stillbirth, or low Apgar score.[77]

CHINESE HERBAL MEDICINE

Herbal medicine is the most important practice of traditional Chinese medicine. It is well accepted as mainstream medical care throughout East Asia but is considered to be complementary or alternative medicine in the West.[79] Typical treatment with Chinese herbal medicine is based on several combined remedies or formulas that have been used in the prevention and treatment of severe nausea and vomiting, infection, threatened abortion, and ectopic pregnancy.[80–82] Hundreds of publications, especially in Chinese medical journals, report the use of Chinese herbal medicine in complicated pregnancies, examples of which are listed in Table 25-1.

TABLE 25-1 Herbal Supplement Use in Pregnancy

	Common Reason for Use
Herbs	
Ginger	Morning sickness and various conditions
Chamomile	Morning sickness, relaxation, and sleep
Cranberry juice	Preventing or treating urinary tract infection
Echinacea or Elderberry	Treating cold or influenza symptoms
Slippery elm	Digestive disorders
Rose hips	Fighting infection
Raspberry leaf	Toning the uterus to prepare for labor
Iron-rich herbs, i.e., oat straw or Echinacea	Preventing anemia
Chinese herbal medicines	
Xiaochaihu plus Fulonggan formula[a]	Treating severe nausea and vomiting
Shapei Huayu formula[b]	Nonsurgical treatment for ectopic pregnancy
Bushenantai drink[c]	Treating threatened abortion
Other supplements	
Fish oil	Increase gestation duration

[a] Contain eight herbs such as Chai hu, Huang qin, Ban xia, Dang shen, and Gan cao.

[b] Contain 11 herbs such as Dan Shen, Tao ren, San leng, and Chi shao.

[c] Contains 12 herbs such as To si zi, Gou qi zi, Du zhong, and Huang qin.

Supplements made from Chinese herbs are marketed and used globally. For example, the Bushenantai drink made from 12 herbs is used to treat threatened abortion[82] and a modified Xiaochaihu formula with 8 herbs is commonly used to treat severe nausea and vomiting during early pregnancy.[80] Chinese herbal medicine also has been used as an adjunct to reduce side effects and toxicity from Western pharmaceuticals. Patients with an ectopic pregnancy were randomly assigned to methotrexate plus mifepristone (N = 125) or to a combination of mifepristone with Shapei Huayu (N = 125), a mixture of 11 Chinese herbs.[81] The success of treatment was evaluated by normal blood β-HCG concentrations, no vaginal bleeding or abdominal pain, and reduced or no abdominal mass by ultrasound. There was no significant difference in the success rate; however, side effects including digestive symptoms, decreased peripheral white cell counts, and liver damage were significantly fewer in the group on the combination treatment. During follow-up, the subsequent successful intrauterine pregnancy rate was higher in the combination treatment (69%) compared to Western medicine alone (49.5%, $P < 0.01$).

Some data suggest that herbal treatments alone or the combination of Chinese herbal medicine with Western medicine carries a significantly lower risk of side effects as does the treatment of ectopic pregnancy described earlier.[81] Other studies have suggested that use of certain common herbal remedies during pregnancy may have untoward consequences.[83] For example, a survey in 3191 Canadian women found that use of flax increased the risk of preterm birth (Adjusted Odds Ratio (AOR) 3.91, 95% CI 1.16–13.14), whereas use of several other herbs (chamomile, peppermint, or green tea) was not associated with increased risk.[83] The problem is that most observational or randomized studies have small sample sizes with inadequate statistical power to detect adverse effects, most of which are relatively uncommon so that case reports are often the only indicator of an adverse experience.[76,84] The recommendation to use herbal products during pregnancy remains controversial.

FISH OIL SUPPLEMENTS

Maternal fatty acids (FAs) are important for fetal growth and development. Both omega (n)-3 and omega (n)-6 polyunsaturated fatty acids (PUFAs)

are essential FAs meaning that they must be consumed in the diet. The essential FA α-linolenic acid gives rise to n 3-PUFA and linoleic acid to n 6-PUFA. The most bioactive forms of n-3 PUFA are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), and the key n-6 PUFA is arachidonic acid. All of the n-3 and n-6 PUFA structures acquired by the fetus must come from the mother across the placenta, either in the form of the essential FAs or their derivatives EPA and DHA.[85] Thus, an enhanced maternal dietary intake of DHA increases the fetal supply and leads to a higher DHA concentration in cord blood.[86] An adequate supply of bioactive FAs needs to be transferred from the mother to the fetus; they are important during the perinatal period for the rapid growth and development of new tissues and organ systems.

Consumption of supplements that contain fish oil as well as eating a diet rich in marine foods that contain n-3-PUFA are associated with beneficial effects including longer gestation duration, improved fetal growth and developmental of visual acuity, cognitive function, and immune phenotype in cohort studies and randomized clinical trials.[85,87] Canadian Inuit with high n-3 PUFA intake have longer gestations (+5.4 days) and increased infant birth weights (+77 g).[88] A trial of 533 Danish women who received fish oil, olive oil, or no supplement by 30 weeks gestation showed taking the fish oil supplements resulted in longer average gestations (+4 days) and infants with higher average weights (+107 g), mostly attributable to increased gestation.[89] The effect of fish oil was strongest with low fish consumption and amounted to +7.4 days longer gestation in this group. A clinical trial of a high-risk, low-income population that was primarily African American showed that the consumption of eggs fortified with DHA late in second trimester increased gestation duration by six days on average.[90] However, a recent meta-analysis of several randomized trials suggested that although the effect of n-3 PUFAs on gestation duration was present, it was weak (+1.5 days).[91] There was little effect of the fish oils when fish consumption was high (−1.6 days).[89] Thus, the hypothesized effect of n-3 PUFA on gestation appears to have a threshold and to be specific to the initiation of idiopathic preterm labor.

Fish oil or use of n-3 PUFA supplements during pregnancy seem clearly to increase the length of gestation, whether such supplements could prevent preterm delivery or other adverse pregnancy outcomes have not been confirmed. A multicenter trial enrolled high-risk women with a history of preterm delivery, fetal growth restriction, or preeclampsia.

Women were randomized to either fish oil or olive oil. Fish oil reduced the recurrence risk of preterm delivery approximately twofold but did not alter the recurrence of the other poor outcomes.[92] Higher doses of n-3 PUFAs (6.1 g/d) in women with threatened preeclampsia or suspected fetal growth restriction showed no effect on these outcomes.[92]

Ecologic studies have indicated that the consumption of large quantities of fish during pregnancy is related to lower blood pressure and thus, in theory, with a lower incidence of pregnancy-induced hypertension. EPA and DHA have been shown to modulate inflammatory and vascular effects and subsequently reduce inflammation-related diseases like cardiovascular disease[93]; it is plausible that n-3 PUFAs could effectively improve vasoconstriction and the endothelial damage related to gestational hypertension and preeclampsia.[85,91] One of the first studies on the topic, The People's League of Health, showed a reduction in risk of preeclampsia, which, because multiple supplementation regimens were used, could not be attributed to the use of the fish oil.[94] Another trial, a multicenter study of fish oil supplements, showed no effect on high blood pressure or the risk of preeclampsia.[91]

An increased n-3 PUFA is needed for fetal growth and development. However, the specific amount of n-3 PUFA to maintain the optimal benefit for the mother and fetus has been difficult to determine, due to the complex metabolism of the PUFA and the preferential use of n-3 PUFA mobilized from the n-3 stored in maternal adipose tissue.[85,95]

Fish provide a source of easily digestible protein and other nutrients, and many fish provide a uniquely rich food source of long-chain PUFA, especially DHA and EPA. The benefit of maternal seafood intake and the competing risk of maternal mercury exposure have been evaluated.[96] Methyl mercury crosses the placenta. The US Food and Drug Administration advised all pregnant women to limit seafood consumption to 340 g/wk to reduce fetal exposure to trace amounts of neurotoxins from methylmercury.[96] This amount of fish should provide approximately 200 mg of DHA per day. Alternative source of DHA including fish oil capsules, which provide variable amounts of DHA ranging from 150 to 1200 mg/d, is low in contaminants like mercury. Many prenatal vitamins contain up to 200–300 mg of DHA/d.[85] Similarly, the consensus of the European Commission on the topic was that dietary intake should be at least 200 mg/d DHA during pregnancy. The commission also recommended screening for maternal dietary inadequacies during first trimester and offering individual counseling during pregnancy and

lactation to women with less desirable diets.[95]

Human Growth and Disease in Later Life

26

David J.P. Barker, MD, PhD, FRS

PROGRAMING

There is now clear evidence that the pace and pathway of early growth and development are major risk factor for the development of chronic diseases. The list of chronic disease that are now suspected of being initiated during early development includes coronary heart disease and type 2 diabetes, which are the focus of this chapter. The list, however, now extends to a wide range of chronic disorders, including certain cancers and chronic infections. This has led to a new "developmental" model for the origins of disease that proposes that nutrition during fetal life, infancy, and early childhood change gene expression and thereby establish functional capacity, metabolic competence, and responses to the later environment, a phenomenon known as "programing."[1–4]

To explore the developmental model for chronic disease required studies of a kind that had not hitherto been carried out. It was necessary to identify groups of men and women now in middle or late life whose size at birth had been recorded at the time. Their birth weight could thereby be related to the later occurrence of disease. In the county of Hertfordshire, UK, from 1911 onwards, when women had their babies they were attended by a midwife, who recorded the birth weight. A health visitor went to the baby's home at intervals throughout infancy, and the weight at 1 year was recorded. Figure 26-1, based on 15, 726 men and women born in the county, shows that mortality from coronary heart disease fell progressively across the normal range of birth weight.[5] In Figure 26-1, mortality rates in each birth weight group are expressed as a percentage of national rates in England and Wales. Similarly to the United States, there is a large

variation in rates between different counties; and Hertfordshire is one of the groups of counties in the south and east that have below average rates. Table 26-1 shows findings for a sample of men in Hertfordshire who had glucose tolerance tests.[6] The percentage with impaired glucose tolerance or type 2 diabetes fell steeply with increasing birth weight. The association between low birth weight and coronary heart disease has now been replicated among men and women in Europe, North America, and India.[7–12] Low birth weight has been shown to predict altered glucose tolerance in studies of men and women around the world.[13–17]. The associations between low birth weight and later disease depend on slow fetal growth rather than premature birth. Among the different cohorts that have been assembled around the world in order to study programing the Helsinki Birth Cohort has some of the most detailed information. The cohort comprises 20,000 men and women who were born in Helsinki, Finland, during 1924–1944. Each of them has detailed birth records and school health records document their growth and health in childhood. Those born after 1933 have records of their growth from birth to seven years, the age of school entry. Health care is free in Finland and any serious illness within the cohort has been documented through the National Hospital Discharge Register. Deaths and their causes are shown in the National Mortality Register. Information about occupation and income is available through the five-year national censuses. Use of medication for chronic illness is also recorded.

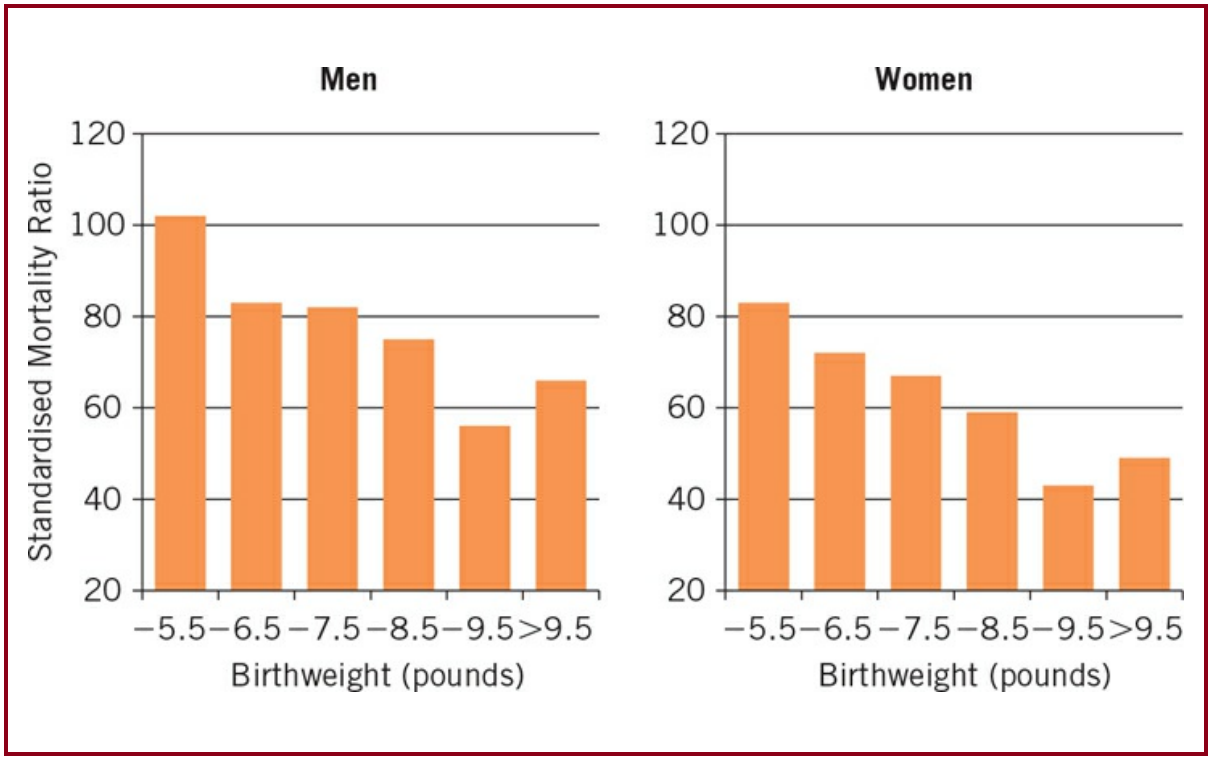

Figure 26-1 Mortality from coronary heart disease in 15,726 men and women in Hertfordshire.

TABLE 26-1 Percentage of Men Aged 64 Years With Impaired Glucose Tolerance or Diabetes According to Weight at Birth in 370 Men in Hertfordshire

Weight (lb)	% of Men With 2-h Glucose of ≥ 7.8 mmol/L	Odds Ratio (95% CI)[a]
≤5.5	40	6.6 (1.5–28)
–6.5	34	4.8 (1.3–17)
–7.5	31	4.6 (1.4–16)
–8.5	22	2.6 (0.8–8.9)
–9.5	13	1.4 (0.3–5.6)
9.5	14	1.0

[a] Adjusted for current body mass index.

BIOLOGICAL BASIS

Like other living creatures in their early life human beings are "plastic" and able to adapt to their environment.[18] The development of the sweat glands provides a simple example of this. All humans have similar numbers of sweat glands at birth but none of them function. In the first three years after birth, a proportion of the glands become functional, depending on the temperature to which the child is exposed. The hotter the conditions, the greater the number of sweat glands that are programed to function. After three years, the process is complete and the number of sweat glands is fixed. Thereafter, the child who has experienced hot conditions will be better equipped to adapt to similar conditions in later life, because people with more functioning sweat glands cool down faster.

This brief description encapsulates the essence of developmental plasticity: a critical period when a system is plastic and sensitive to the environment, followed by loss of plasticity and a fixed functional capacity. For most organs and systems, the critical period occurs in utero. Among the major organs only the brain, liver, and immune system remain plastic. There are good reasons why it may be advantageous in evolutionary terms for the body to remain plastic during development. It enables the

production of phenotypes that are better matched to their environment than would be possible if the same phenotype was produced in all environments. Developmental plasticity is defined as the phenomenon by which one genotype can give rise to a range of different physiological or morphological states in response to different environmental conditions during development.[19] A baby's responses to malnutrition include slowing of growth and altered metabolism, which enable it to survive. As Mellanby noted long ago, the ability of a human mother to nourish her baby is partly determined when she herself is *in utero*, and by her childhood growth.[20] The human fetus therefore responds not only to conditions at the time of the pregnancy but to conditions a number of decades before.

Until recently, we have overlooked a growing body of evidence that systems of the body that are closely related to adult disease, such as the regulation of blood pressure, are also plastic during early development. In animals, it is surprisingly easy to produce lifelong changes in the physiology and metabolism of a fetus by minor modifications to the diet of the mother before and during pregnancy.[21–23]

The different size of newborn human babies exemplifies plasticity. The growth of babies has to be constrained by the size of the mother, otherwise, normal birth could not occur. Small women have small babies: in pregnancies after ovum donation they have small babies even if the woman donating the egg is large.[24] Babies may be small because their growth is constrained in this way or because they lack the nutrients for growth. As McCance wrote, "The size attained *in utero* depends on the services which the mother is able to supply. These are mainly food and accommodation."[25] Research into the developmental origins of disease has focused on the nutrient supply to the baby, while recognizing that other influences, such as hypoxia, stress, and maternal size also influence fetal growth.[26] The availability of nutrients to the fetus is influenced by the mother's nutrient stores and metabolism, as well as by her diet during pregnancy. In developing countries many babies are undernourished because their mothers are chronically malnourished. Despite current levels of nutrition in Western countries, the nutrition of many fetuses and infants remains suboptimal because the nutrients available are unbalanced or because their delivery is constrained by maternal metabolism. Globally, size at birth in relation to gestational age is a marker of fetal nutrition.[26]

DEVELOPMENTAL ORIGINS HYPOTHESIS

The developmental origins hypothesis proposes that a range of chronic diseases, including coronary heart disease, stroke, hypertension, and type 2 diabetes, together with certain cancers and chronic infections, originate in developmental plasticity, in response to under nutrition during fetal life and infancy.[2,3] Why should fetal responses to under nutrition lead to disease in later life? The general answer is clear: "life history theory", which embraces all living things, states that during development there is never enough resource to perfect every trait. If a plant in your garden seeks more moisture by growing deeper roots, it will do so at the expense of its stem and leaves. In humans, increased allocation of energy to one trait, such as brain growth necessarily reduces allocation to one or more other traits, such as tissue repair processes. Smaller babies, who have had a lesser allocation of energy, must incur higher costs and these, it seems, include disease in later life. A more specific answer to the question is that people who were small at birth are vulnerable to later disease through three kinds of process. First, they have less functional capacity in key organs, such as the kidney: one theory holds that hypertension is initiated by the reduced number of nephrons, the functional units of the kidney that are found in people who were small at birth.[27] A second process is the setting of hormones and metabolism. An undernourished baby may establish a "thrifty" way of handling food. Insulin resistance, which is associated with low birth weight, may be viewed as persistence of a fetal response by which blood glucose concentrations were maintained for the benefit of the brain but at the expense of glucose transport into the muscles and muscle growth.[28]

A third link between low birth weight and later disease is that people who were small at birth are more vulnerable to adverse environmental influences in later life. Observations on animals show that the environment during development permanently changes not only the body's structure and function but also its responses to environmental influences encountered in later life.[19] Table 26-2 shows the effect of low income in adult life on coronary heart disease among men in Helsinki.[29] As expected, men who had a low taxable income had higher rates of the disease. There is no agreed explanation for this but the association between poverty and coronary heart disease is a major component of the social inequalities in health in many western countries. Among the men in Helsinki, however, the association was confined to one quarter of the men who had slow fetal growth and were thin at birth, defined by a index (birth weight/length^3) of less than 26 kg/m^3 (Table 26-2). Among men who were not thin at birth,

coronary heart disease was not associated with income, which implies that these men, the majority, were resilient to the effects of low income.

TABLE 26-2 Hazard Ratios (95% CI) for Coronary Heart Disease in 3629 Men in Helsinki According to Ponderal Index at Birth (Birth Weight/Length^3) and Household Income in Adult Life

Household Income Pounds Sterling per Year	Ponderal Index ≤ 26.0 kg/m^3 (*n* = 1475)	Ponderal Index < 26.0 kg/m^3 (*n* = 2154)
<15,700	1.00	1.19 (0.65–2.19)
15,700	1.54 (0.83–2.87)	1.42 (0.78–2.57)
12,400	1.07 (0.51–2.22)	1.66 (0.90–3.07)
10,700	2.07 (1.13–3.79)	1.44 (0.79–2.62)
≤8,400	2.58 (1.45–4.60)	1.37 (0.75–2.51)
P for trend	<0.001	0.75

One explanation for these findings emphasizes the psychosocial consequences of a low position in the social hierarchy, as indicated by low income and social class, and suggests that perceptions of low social status and lack of success lead to changes in neuro endocrine pathways and hence to disease.[30] The findings in Helsinki seem consistent with this. People who were small at birth are known to have persisting alterations in responses to stress, including raised serum cortisol concentrations.[31] It is suggested that persisting small elevations of cortisol concentrations for many years may have effects similar to those seen when tumors lead to more sudden, large increases in glucocorticoid concentrations. People with Cushing's syndrome, the result of over activity of the adrenal cortex, are insulin-resistant and have raised blood pressure, both of which predispose to coronary heart disease.

INFANT AND CHILDHOOD GROWTH

Table 26-2 shows the early growth of men and women who were either admitted to hospital with coronary heart disease or died from it.[32] They belong to a cohort of 8760 people who were born in Helsinki, Finland during 1934–1944. Their mean height, weight, and body mass index (BMI,

weight/height^2) at each month from birth to 2 years of age, and at each year from 2 to 11 years of age, are expressed as standard deviations (*z*-scores). The mean *z*-score for the cohort is set at zero and a child maintaining a steady position as tall or short, or fat or thin, in relation to other children would follow a horizontal path on the figure. At birth the mean body size of the boys who developed coronary heart disease in their later lives was approximately 0.2 standard deviations below the average and they were thin. Between birth and two years of age, mean *z*-scores for each measurement fell, so that at two years the boys were thin and short. After 2 years of age their *z*-scores for body mass index began to increase and continued to do so. In a simultaneous regression, both low body mass index at birth and at 2 years of age, and high body mass index at 11 years of age were associated with later coronary events.[32] This suggests that growth during fetal life, infancy, and childhood each contribute to the genesis of coronary heart disease.

As with the boys, the mean body size of the girls who later had coronary events was below the average (Figure 26-2). They tended to be short at birth rather than thin, but their mean *z*-scores for body mass index fell progressively after birth so that, like the boys, they were thin at 2 years of age, though not short. After 4 years of age their *z*-scores for weight and body mass index began to increase and continued to do so, reaching the average at approximately 8 years of age, and exceeding it thereafter. Similarly to the boys, in a simultaneous regression body size at each of the three ages, birth two and eleven years were independently associated with later coronary events.[32]

In Table 26-3 findings for boys and girls have been combined to show the simultaneous effect of birth weight and body mass index at 2 years of age, divided into thirds, on hazard ratios for coronary events. The highest hazard ratios are among subjects with birth weights below 3.0 kg and body mass indices at 2 years of age of 17 kg/m^2 or less. Table 26-4 shows the simultaneous effects of body mass index at 2 and 11 years of age. The highest hazard ratios were among people with body mass indices below 16 kg/m^2 at 2 years of age and above 17.5 kg/m^2 at 11 years of age. The hazard ratios in Table 26-3 and Table 26-4 were little changed if they were adjusted for socio-economic status or income in adult life; and they are a further demonstration of that coronary heart disease is associated with both prenatal and postnatal growth.[33]

The rapid weight gain after the age of 2 years that characterizes the growth of children who later develop coronary heart disease (Figure 26-2)

is thought to reflect “compensatory” growth.

If the growth of a fetus, infant or child falters because of malnutrition or other adversity it has the ability, once the adversity has ceased, to return to its growth trajectory by accelerated growth. The ability to mount rapid “compensatory” growth following growth faltering is common in animals and familiar to farmers. It necessarily has costs. If energy is allocated to rapid growth, the allocation to some other developmental activity must be reduced. In animals, compensatory growth has a wide range of physiological and metabolic costs that include reduced quality of tissues and organs, such as bone, heart, kidneys, and premature death. Little is known about these costs in humans.[3]

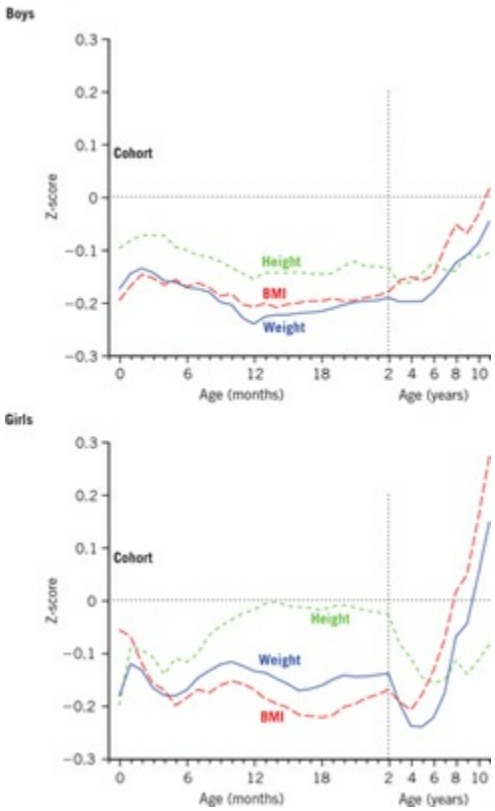

Figure 26-2 Mean *z*-scores for height, weight, and body mass index in the first 11 years after birth among boys and girls who had coronary heart disease as adults. The mean values for all boys and all girls are set at zero, with deviations from the mean expressed as standard deviations (*z*-scores).

TABLE 26-3 Hazard Ratios (95% confidence

intervals) for Coronary Heart Disease According to Birth Weight and Body Mass Index (BMI) at 2 Years of Age for Boys and Girls Combined

	BMI at Age 2 (kg/m^2)		
Birth Weight (kg)	**<16**	**16–17**	**>17**
<3.0	1.9 (1.3–2.8)	1.9 (1.2–3.0)	1.3 (0.7–2.2)
3.0–3.5	1.5 (1.0–2.1)	1.6 (1.1–2.2)	1.2 (0.8–1.8)
>3.5	1.7 (1.2–2.5)	1.5 (1.1–2.2)	1.0

TABLE 26-4 Hazard Ratios (95% confidence intervals) for Coronary Heart Disease According to Body Mass Index (BMI) at 2 and 11 Years of Age for Boys and Girls Combined

	BMI at Age 11 (kg/m^2)		
BMI at Age 2 (kg/m^2)	**<16**	**16–17.5**	**>17.5**
<16	1.6 (0.8–3.3)	2.4 (1.2–4.9)	3.0 (1.4–6.3)
16–17	1.4 (0.7–3.1)	1.6 (0.8–3.3)	1.9 (0.9–3.9)
>17	1.0	1.3 (0.6–2.7)	1.1 (0.5–2.3)

One explanation of the associations between coronary heart disease and small body size at birth and thinness at 2 years of age is that babies who are thin or short at birth and during infancy lack muscle, a deficiency that will persist into childhood as there is little cell replication in muscle after around one year of age.[34] Rapid weight gain in childhood may lead to a disproportionately high fat mass in relation to muscle mass. This could underlie the strong associations between low birth weight, low body mass index at 2 and high body mass index at 11 and later insulin resistance, which was found when a sub-sample of 2,003 subjects in the Helsinki cohort were examined at the age of 62 years.[32]

TYPE 2 DIABETES AND HYPERTENSION

Through their lives people who were small at birth remain biologically different to people who were large: these differences include an increased

susceptibility to type 2 diabetes and hypertension. Table 26-5 shows odds ratios for these two disorders according to birth weight and fourths of body mass index at age 11 years.[33] The two disorders are associated with the same general pattern of growth as coronary heart disease.[32] Risk of disease falls with increasing birth weight and rises with increasing childhood body mass index. The Helsinki Birth Cohort allows estimation of the strength of these effects.[33] If each individual in the Helsinki Birth Cohort had been in the highest third of birth weight and had decreased their standard deviation score for body mass index between ages 3 and 11 years, the incidence of type 2 diabetes would have been halved. This demonstrates the potential power of interventions during development.

The associations between low birth weight and type 2 diabetes shown in Table 26-5 have been found in other studies.[6,13–17] The association with hypertension has also been found in other studies.[35] There is a substantial literature showing that birth weight is associated with differences in insulin sensitivity and blood pressure within the normal range.[6,13,17,36] These differences are found in children and adults but they tend to be small. A 1kg difference in birth weight is associated with around 3mmHg difference in systolic pressure. The contrast between this small effect and the large effect on hypertension (Table 26-5) suggests that structural or functional changes that are associated with poor fetal growth, and that tend to elevate blood pressure after birth, have a small influence on blood pressure within the normal range because counter-regulatory mechanisms maintain normal levels. Over time, however, as the initial changes progress with age, these mechanisms are no longer able to maintain homeostasis. This may initiate a cycle of rising blood pressure, further progression of the initial changes and further rise in blood pressure.[27,37] Rapid increase in body size after birth may exacerbate glomerular injury because greater body size leads to increased excretory load and glomerular hyperfiltration.[38] Direct evidence in support of this has come from a study of the kidneys of people killed in road accidents. Those being treated for hypertension had fewer, but larger, glomeruli.[39]

TABLE 26-5 Odds Ratios (95% confidence intervals) for Type 2 Diabetes and Hypertension According to Birth Weight and Body Mass Index (BMI) at Age 11 Years

	BMI at Age 11 (kg/m^2)

Birth Weight (kg)	<15.7	–16.6	–17.6	>17.6
Type 2 diabetes (698 cases)				
<3.0	1.3 (0.6–2.8)	1.3 (0.6–2.8)	1.5 (0.7–3.4)	2.5 (1.2–5.5)
−3.5	1.0 (0.5–2.1)	1.0 (0.5–2.1)	1.5 (0.7–3.2)	1.7 (0.8–3.5)
−4.0	1.0 (0.5–2.2)	0.9 (0.4–1.9)	0.9 (0.4–2.0)	1.7 (0.8–3.6)
>4.0	1.0	1.1 (0.4–2.7)	0.7 (0.3–1.7)	1.2 (0.5–2.7)
Hypertension (2997 cases)				
<3.0	2.0 (1.3–3.2)	1.9 (1.2–3.1)	1.9 (1.2-3.0)	2.3 (1.5–3.8)
−3.5	1.7 (1.1–2.6)	1.9 (1.2–2.9)	1.9 (1.2-3.0)	2.2 (1.4–3.4)
–4.0	1.7 (1.0–2.6)	1.7 (1.1–2.6)	1.5 (1.0-2.4)	1.9 (1.2–2.9)
>4.0	1.0	1.9 (1.1–-3.1)	1.0 (0.6-1.7)	1.7 (1.1–2.8)

FETAL NUTRITION

Size at birth is the product of the fetus's trajectory of growth, which is set at an early stage in development, and the mater no-placental capacity to supply sufficient nutrients to maintain this trajectory. A rapid trajectory of growth increases the fetus's demand for nutrients.[26] This demand is greatest late in pregnancy but the trajectory is thought to be primarily determined by genetic and environmental effects in early gestation. Experiments in animals have shown that alterations in maternal diet around the time of conception can change the fetal growth trajectory.[22] The sensitivity of the human embryo to its environment is being increasingly recognized with the development of assisted reproductive technology.[40] The trajectory of fetal growth is thought to increase with improvements in periconceptional nutrition, and is faster in male fetuses. The consequent greater vulnerability of male fetuses to under-nutrition may contribute to the shorter lives of men.[41]

MATERNAL NUTRITION

The graded relation between birth weight and later disease (Figure 26-1)

implies that variations in the supply of food from normal healthy mothers to normal healthy babies have major implications for the long-term health of the babies.[4] A baby does not depend on the mother's diet during pregnancy: that would be too dangerous a strategy. Rather it lives off her stored nutrients and the turnover of protein and fat in her tissues.[42] These are related to her body composition and therefore reflect her lifetime nutrition.

Studies in Europe and India have shown that high maternal weight and adiposity are associated with the development of insulin deficiency, type 2 diabetes, and coronary heart disease in the offspring.[43–45] There is also an increasing body of evidence showing that low maternal weight, body mass index and skin fold thickness are associated with insulin resistance and raised blood pressure in the offspring.[46–52] One of the metabolic links between maternal body composition and birth size is protein turnover. Women with a low lean body mass have low rates of protein turnover in pregnancy.[53]

Although a mother's diet during pregnancy is not closely linked to the birth weight of her baby it can program the baby. Follow-up studies of people who were in utero during the war-time famine in Holland have shown that, although the babies' birth weights were little affected, the severe maternal caloric restriction at different stages of pregnancy was variously associated with obesity, dyslipidemia, insulin resistance and coronary heart disease in the offspring.[46] In these studies maternal rations with a low protein density were associated with raised blood pressure in the adult offspring.[54] This adds to the findings of studies in Aberdeen and Mother well, UK, which showed that maternal diets with either a low or a high ratio of animal protein to carbohydrate were associated with raised blood pressure in the offspring during adult life.[47,55] While it may seem counterintuitive that a high-protein diet should have adverse effects, these findings are consistent with the results of controlled trials of protein supplementation in pregnancy, which show that high protein intakes are associated with reduced birth weight.[56] One possibility is that these adverse effects are a consequence of the metabolic stress imposed on the mother by an unbalanced diet in which high intakes of essential amino acids are not accompanied by the micronutrients required to utilize them.

THE ROLE OF THE PLACENTA

A baby's birth weight depends not only on the mother's nutrition but also

on the placenta's ability to transport nutrients to it from its mother. The placenta seems to act as a nutrient sensor regulating the transfer of nutrients to the fetus according to the mother's ability to deliver them, and the demands of the fetus for them.[57] The weight of the placenta, and the size and shape of its surface, reflect its ability to transfer nutrients. The shape and size of the placental surface at birth has become a new marker for chronic disease in later life.[58] The predictions of later disease depend on combinations of the size and shape of the surface and the mother's body size. Particular combinations have been shown to predict coronary heart disease,[59] hypertension,[60] chronic heart failure[61] and certain forms of cancer.[62] The placenta is the most varied of all human organs. Variations in placental size and shape reflect variations in the normal processes of its development, including implantation, unplugging of the spiral arteries, and the growth and compensatory expansion of the chorionic plate(Figure 26-3). These variations are accompanied by variations in nutrient delivery to the fetus. Figure 26-3 also shows potential effects of exposure to maternal hormones during gestation, but this is outside the scope of this review.

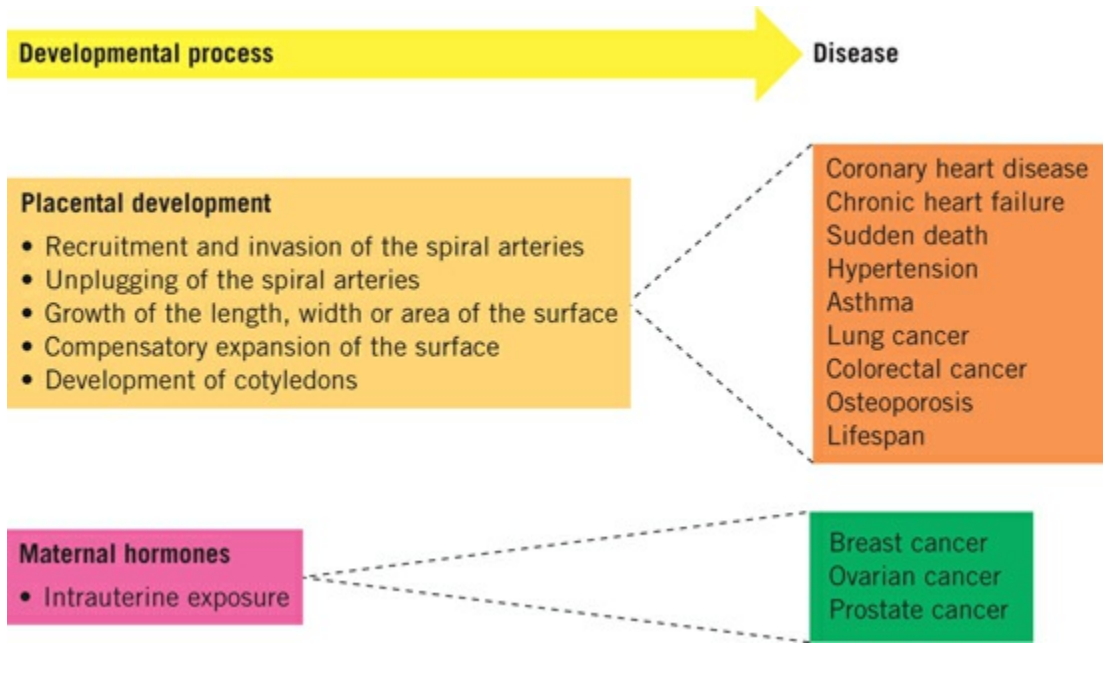

Figure 6-3 Variations in the normal processes of development and later chronic disease.

TABLE 26-6 Mean Systolic Blood Pressure (mmHg)

of Men and Women Aged 50, Born After 38 Weeks Completed Weeks of Gestation, According to Placental Weight and Birth Weight					
	Placental Weight, lb (g)				All
Birth Weight, lb (kg)	≤1.0 (454)	–1.25 (568)	–1.5 (681)	>1.5 (681)	
−6.5 (2.9)	149	152	151	167	152
−7.5 (3.4)	139	148	146	159	148
>7.5 (3.4)	131	143	148	153	149
All	144	148	148	156	149

Table 26-6 shows the systolic pressures of a group of men and women who were born at term in Preston, UK.[63] They are grouped according to their birth weight and placental weight. As expected systolic pressures fall between those with low and high birth weight. In addition the pressures increase with increasing placental weight. People with a mean systolic pressure of 150 mmHg or more, a level used to define hypertension, comprise a group who as babies were relatively small in relation to the size of their placentas. In Table 26-6, the fall in pressures of 10 mmHg across the range of birth weight is statistically opposed by the rise of 12 mmHg associated with increasing placental weight. These large trends are concealed when all pressures at a given birth weight are combined as in the right-hand column.

In studies of children and adults, the association between placental enlargement and raised blood pressure has been inconsistent.[64] Animal studies offer a possible explanation of this. In sheep the placenta enlarges in response to moderate under nutrition in mid-pregnancy.[65] This is thought to be an adaptive response to extract more nutrients from the mother. It is not, however, a consistent response but occurs only in ewes that were well nourished when they conceived. In the Helsinki, birth cohort people who had both hypertension and type 2 diabetes had low placental weight at birth, while those with hypertension alone had large placental weight in relation to birth weight.[65] These statistically opposing trends may also explain why some studies have failed to find associations between placental weight and later blood pressure.

PATHWAYS TO DISEASE

New studies, especially the Helsinki studies with their detailed information on child growth and socioeconomic circumstances, increasingly suggest that the pathogenesis of chronic disease may depend on a series of interactions occurring at different stages of development.[66] To begin with, the effects of the genes acquired at conception may be conditioned by the early environment. Table 26-7 is based on a study of 476 elderly people in Helsinki.[67] It shows mean fasting plasma insulin concentrations according to which of two polymorphisms of the peroxisome proliferators-activated receptor (PPAR)-γ gene is present. The Pro12Pro polymorphism is known to be associated with insulin resistance, indicated by elevated fasting plasma insulin concentrations. Table 26-7 shows, however, that this effect occurs only among men and women who had low birth weight. Conversely, low birth weight has been consistently linked to later insulin resistance,[28] but Table 26-7 shows that this effect occurs only among people with the Pro12Pro polymorphism. As birth weight serves as a marker of fetal nutrition,[26] this gene birth weight interaction may reflect a gene-nutrient interaction during development. The rise of the science of epigenetics is confirming that the expression of genes is contingent on the environment.

The effects of the intrauterine environment on later disease are conditioned not only by events at conception but also by events after birth. Table 26-5 shows how the effects are conditioned by childhood body mass index. Table 26-2 shows that the effects of low ponderal index at birth are conditioned by living conditions in adult life. Table 26-8, based on findings in the Helsinki Birth Cohort, shows how the effects of low birth weight on later hypertension are conditioned by living conditions in childhood, indicated by the occupational status of the father.[68] Among all the men and women, low birth weight was associated with an increased incidence of hypertension, as has been shown before.[36] This association, however, was present only among those who were born into families where the father was a laborer or of lower middle class.

TABLE 26-7 Mean Fasting Insulin Concentrations (pmol/L) in Elderly People in Helsinki According to PPAR-γ Gene Polymorphism and Birth Weight

	Birth Weight (kg)

	<3.0	3.0–3.5	<3.5	*P* for Trend

>4000	11.1	15.6	15.7	0.11
P for trend	<0.001	0.05	0.79	

It seems that the pathogenesis of chronic disease cannot be understood within a model in which risks associated with adverse influences at different stages of life add to each other. Rather, disease is the product of branching paths of development. The environment triggers the branching. The pathways determine the vulnerability of each individual to what lies ahead.[38,69]

A clinical study within the Helsinki Birth Cohort showed that two different paths of fetal, infant, and childhood growth preceded the development of hypertension in adult life. In one, which was associated with more severe hypertension in people who tended to be overweight, small body size at birth and during infancy were followed by rapid weight gain, so that at age 11 years the children's body size was around the average. This is the same path of growth that leads to insulin resistance and coronary heart disease (Figure 26-2). In the other path of growth, which was associated with less severe hypertension, slow linear growth in utero and during infancy were followed by persisting small body size so that at age eleven years the children were short and thin. A similar path of growth leads to stroke.[70] One possible process underlying this is that slow growth is associated with impaired development of the cerebral

vasculature during a period of rapid brain growth or with altered lipid metabolism and the development of an atherogenic liver profile.[71] The two different paths of growth may lead to hypertension through different biological mechanisms and may produce two groups of patients who respond differently to medication.

We are beginning to understand the processes through which different paths of development initiate hypertension.[38] The changes occur at different levels and include allocation of stem cells and alteration of gene expression in the embryo, changes in renal growth, and alteration in haemostatic set-points that control blood pressure. These changes can make the affected systems more vulnerable to disruptive influences in postnatal life, which include rapid weight gain, oxidative stress, environmental stress, and a high salt intake.

CONCLUSION

Under the new developmental model for the origins of chronic disease, the causes to be identified are linked to normal variations in the processes of development that lead to variations in the supply of nutrients to the baby. These variations program the function of a few key systems that are linked to chronic disease-the immune system, anti-oxidant defences, inflammatory responses, the number and quality of stem cells, neuro endocrine settings, and the balance of the autonomic nervous system. There is not a separate cause for each different disease. Rather one cause can have many different disease manifestations. Which chronic disease originates during development may depend more on timing than on qualitative differences in exposures.

Exploration of the developmental model will illuminate people's differing responses to the environment through their lives. As René Dubos wrote long ago "The effects of the physical and social environments cannot be understood without knowledge of individual history."[72] The model will also illuminate geographical and secular trends in disease. Because human growth has changed over the past two hundred years so different chronic diseases have risen and then fallen, to be replaced by other diseases.[73,74] Much remains to be done. We are only at the beginnings of an understanding of the costs of compensatory growth in humans. Our knowledge of the structure and function of the normal human placenta is fragmentary.

Coronary heart disease, type 2 diabetes, breast cancer, and other chronic diseases are unnecessary. Their occurrence is not mandated by

genes passed down to us through thousands of years of evolution. Chronic diseases are not the inevitable lot of humankind. They are the result of the ever-changing pattern of human development. We could readily prevent them, had we the will to do so. Prevention of chronic disease and an increase in healthy aging require improvement in the nutrition of girls and young women. Many babies in the womb in the western world today are receiving unbalanced and inadequate diets. Many babies in the developing world are malnourished because their mothers are chronically malnourished. Protecting the nutrition and health of girls and young women should be the corner stone of public health. Not only will it prevent chronic disease but also it will produce new generations who have better health and wellbeing through their lives.

Nutrition and Development of the Fetus: Carbohydrate and Lipid Metabolism

27

William W. Hay, Jr, MD, Laura D. Brown, MD, Stephanie R. Wesolowski, PhD, Paul J. Rozance, MD

NUTRITION AND DEVELOPMENT OF THE FETUS: CARBOHYDRATE AND LIPID METABOLISM

The rapid rates of metabolism and growth of the placenta and fetus require ready sources of carbon for energy production and energy storage. Maternal plasma glucose provides most of the carbon for placental and fetal energy requirements. As much as 20%–30% of the amino acids taken up by the fetus from the placenta may be oxidized, providing the additional carbon necessary to meet the fetal requirements for oxidation. Lactate that is produced in the placenta (mostly from glucose) also serves as a carbon source for the fetus. Twenty to forty percent of glucose carbon is deposited in growing body tissues; most of this goes to glycogen, some to protein, and some to adipose tissue. Lipid, on the other hand, appears to

be directed primarily to growth and development of adipose tissue, as there is little capacity to oxidize long-chain fatty acids in fetal tissues. Lipids also account for fetal growth through the provision of essential fatty acids supplied to developing structural membranes.

Based on experimental data from late-gestation fetal sheep and estimated data from term human fetuses, it is possible to construct reasonable estimates for the rates of carbon supply to the fetus from glucose (including products of glucose metabolism in the placenta such as lactate and fructose) and amino acids, as well as for fatty acids, and to compare these rates with requirements for energy production and storage. Such estimates are shown in Table 27-1[1–3]

TABLE 27-1 Nutrient Substrate Balance in Late Gestation Fetal Sheep and Humans

Carbon-Calorie Balance	Carbon (g/kg/d)	Calories (kcal/kg/d)
Requirement		
Accretion in carcass: nonfat (sheep)	3.2	32
Accretion in carcass: nonfat (human)	3.2	32
Accretion in carcass: fat (human)	3.5	33

CARBOHYDRATES

Sources of Glucose for the Placenta and Fetus

Maternal Glucose Supply

Maternal plasma glucose provides all of the glucose for the placenta and fetus, except under pathological conditions of prolonged maternal hypoglycemia, placental insufficiency, or fetal hypoxemia when the fetus can produce its own glucose by glycogenolysis or gluconeogenesis. The placenta also can use its own glycogen for glycolysis, but there is insufficient glucose-6-phosphatase in the placenta to produce significant amounts of glucose from placental glycogen into the fetal circulation. Qualitative evidence demonstrating that maternal glucose is the sole source of glucose for the placenta and fetus under normal conditions comes from studies in which tracers of glucose that are infused into the mother have the same specific activity or enrichment (ratio of tracer glucose to unlabeled glucose) in blood sampled from the fetus, indicating no dilution of fetal glucose with glucose other than from the maternal circulation.[4] Quantitative evidence to support these observations has come from tracer studies in the fetal sheep during fed, normoglycemic conditions.[5] In these studies, net uptake of glucose by the fetus from the placenta equals fetal glucose utilization; that is, there is no source of glucose for fetal glucose utilization other than what comes from the mother by way of the placenta.

Fetal Glucose Production

Only after prolonged periods (several days to weeks) of decreased fetal glucose supply, producing sustained fetal hypoglycemia and hypoinsulinemia, does fetal glucose utilization exceed supply, demonstrating a new source of fetal glucose production.[6,7] However, most species appear to have sufficient functional activities of hepatic gluconeogenic enzymes in late fetal life such that they are prepared to initiate gluconeogenesis, except the rat, in which cytosolic phosphoenolpyruvate carboxykinase (PEPCK) develops only after birth.[8] Thyroid hormone is essential for gluconeogenesis, acting on both the hepatic gluconeogenic pathways and the mechanisms activating

gluconeogenesis. Thyroid hormone effects include up-regulation of catecholamine secretion and increased or maintained concentrations of enzymes necessary for glucose production such as glucose-6-phosphatase, fructose diphosphatase, and alanine aminotransferase.[9] Cortisol concentrations increase approximately 48 hours before birth and correlate with increased endogenous glucose production rates and catecholamine concentrations in fetal sheep.[10] An increase in fetal cortisol concentration, in addition to increased catecholamines, is required for activating fetal gluconeogenesis in response to maternal fasting. A variety of models have shown that normal fetal concentrations of insulin, in addition to glucose, suppress fetal glucose production, but this also requires intact hormonal regulation, including glucagon (necessary for gluconeogenesis) as well as cortisol and catecholamines (necessary for glycogenolysis).[10]

As at all stages of life, fetal glucose production also can come from glycogenolysis. The principal source of fetal hepatic glycogen is fetal plasma glucose. Nonglucose precursors such as circulating lactate and certain amino acids such as alanine, serine, and glutamine contribute to about 10% of glycogen formation (at least in the fetal sheep) by the indirect pathway of reverse glycolysis. Glycogen accumulates progressively toward term in most organs.[11] Lung glycogen content decreases late in gestation, however, presumably as a part of surfactant production, although this issue is controversial. Glycogenolysis in the fetus is rapidly activated by catecholamine infusion, glucagon injection, and hypoxemia/ischemia; all of the enzymes necessary for glycogenolysis are present early in gestation.[12]

Mechanisms of Placental Glucose Uptake and Transport

A principal action of fetal glucose production, regardless of cause or mechanism, is to divert uterine glucose supply to the placenta. As shown in (Figure 27-1),[1] an increase in fetal glucose concentration that is independent of the maternal glucose concentration can separately regulate the partition of uterine glucose uptake into glucose transfer to the fetus and uteroplacental glucose consumption. This observation demonstrates complex regulation of glucose uptake, metabolism, and transfer to the fetus by the placenta.

Maternal Glucose Concentration

Glucose enters the placenta and fetus from the maternal circulation according to concentration-dependent mechanisms, making the maternal

plasma glucose concentration the principal regulator of placental and fetal glucose supply.[1] Increasing consumption of glucose by the growing placenta and fetus tends to decrease maternal glucose concentrations as their growth increases over gestation, but this is balanced by the development of physiological maternal insulin resistance and glucose intolerance caused by certain hormones (e.g., placental lactogen, progesterone, prolactin, estrogen, and glucocorticoids) and certain competitive substrates (e.g., fatty acids) that tend to increase maternal glucose concentrations.[13] This balance is variable, but generally involves a gradual decline in maternal glucose concentration in late second trimester to early third trimester, followed by a gradual increase in late third trimester. In women who develop overt diabetes mellitus with insulin resistance and glucose intolerance during late gestation, insulin resistance appears to be the primary defect. The mechanism for this insulin resistance involves reduction in the insulin signal transduction cascade independent of hormonal influence, as well as potentially significant inhibitory effects of placental growth hormone.[14,15]

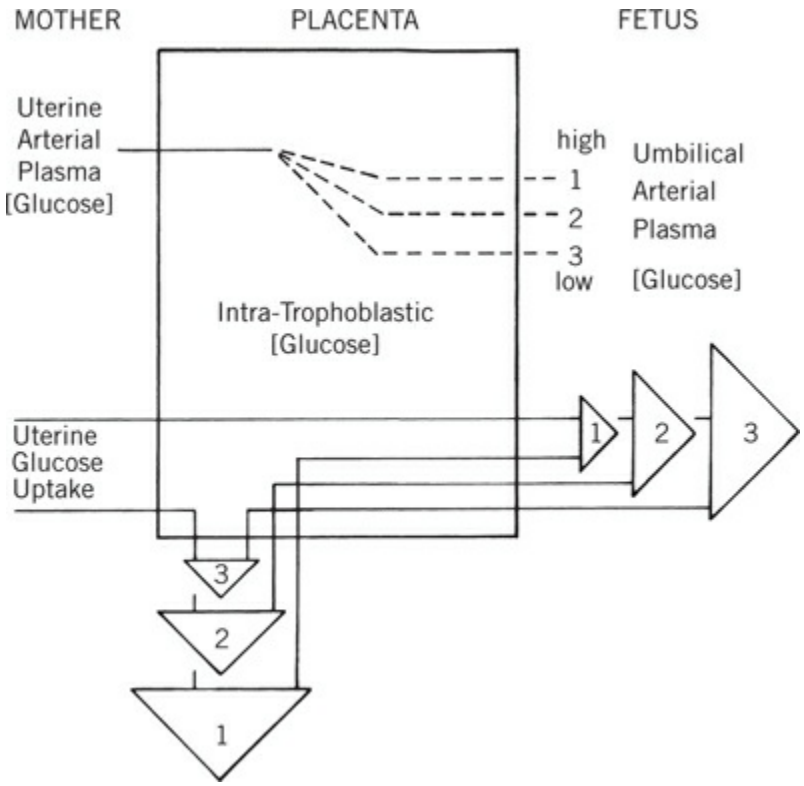

Figure 27-1 Schema of effects of fetal glucose concentration of placental glucose transfer to the fetus and uteroplacental glucose

consumption, adapted from data in sheep. A decrease in fetal glucose concentration relative to maternal glucose concentration promotes maternal-to-fetal glucose transfer at the expense of uteroplacental glucose consumption. These findings demonstrate a reciprocal relationship between placental glucose transfer and uteroplacental glucose consumption that is determined by the fetal glucose concentration. Reproduced with permission of the Nutrition Society.[1]

Placental Glucose Transporters

Glucose uptake and transport by the placenta are mediated by selective glucose transporters. Glut-1 (all species) and Glut-3 (human, rat, sheep) isoforms have been identified at maternal- facing microvillous trophoblast and fetal-facing basal trophoblast membranes. In the human placenta, Glut-1 is the principal transporter at the maternal-facing microvillous membrane, while Glut-3 predominates on the fetal-facing basal membrane or localized in extravillous trophoblast and villous cytotrophoblast cells.[16] However, quantitative distribution has varied among studies and species.[17]

Glut-4 also has been found in the human placenta, probably mostly on fibroblasts, but not consistently on either surface of the trophoblast. There is no evidence, however, that insulin in either the maternal or the fetal circulation increases placental glucose uptake or transfer to the fetus. These observations define the placenta as a nonclassical target organ of insulin regulation of glucose metabolism.

Changes in transporter expression can occur in response to changes in glycemia, particularly when the glycemic changes are chronic. For example, hyperglycemia has been shown to down-regulate the Glut-1 glucose transport system in the placenta in vitro.[18] In contrast, hyperglycemia in diabetic pregnancies that enhances fetal glucose-stimulated insulin and insulin-like growth factor (IGF)-1 production appears also to promote Glut-1 at the fetal-facing basal trophoblast membrane, thereby maintaining an increased placental glucose transport capacity.[19] Hyperglycemia itself also may promote further hyperglycemia in pregnancy. For example, pregnant women with gestational diabetes mellitus release greater amounts of tumor necrosis factor alpha (TNFω) from both the placenta and the maternal adipose tissue in response to high glucose. TNFω specifically interrupts the insulin signal transduction pathway leading to insulin resistance, glucose intolerance, and progression of hyperglycemia.[20] In other species, different patterns have been observed. For example, in the sheep, chronic hyperglycemia was

associated with reduced Glut-1 and Glut-3 concentrations and with increased glucose uptake by the uteroplacenta from the mother. There was no change in fetal glucose uptake, however. In contrast, chronic hypoglycemia decreased placental Glut-1 concentrations but did not appear to change placental Glut-3 concentrations, although uterine, uteroplacental, and fetal glucose uptake rates were decreased.[21] Thus, changes in placental Glut expression are not necessarily directly related to placental glucose transport to the fetus, which appears to exert independent control over its rate of glucose uptake.

Maternal nutritional patterns during gestation also affect the expression of placental glucose transporters. In sheep, for example, early gestational nutrient restriction decreases placental size but does not change placental weight-specific Glut-1 transporter abundance. When such sheep were re-fed later in gestation, both placental mass and Glut-1 abundance increased when fed to sufficiency but neither increased if the ewes were over-fed.[22] Nutrient restriction studies in the pregnant rat have shown no change in placental Glut-1 expression, but did show reduced Glut-3 expression. An additional study compared rodent and ovine placental Glut-1 responses to changes in glucose.[23] In the rat, six days of sustained hyperglycemia caused no change in Glut-1 protein levels, whereas three days of intrauterine growth restriction (IUGR) with fetal hypoglycemia and ischemic hypoxia decreased Glut-1 levels by 50%. In pregnant sheep, maternal and fetal hyperglycemia caused an initial threefold increase in Glut-1 with a persistent decline over the next two to three weeks, whereas maternal and fetal hypoglycemia led to a 30% to 50% decline in placental Glut-1 levels. In a rat placental cell line, high glucose concentrations decreased Glut-1 concentrations, counteracted in part by exposure to low oxygen concentrations.

Clearly, placental glucose transfer to the fetus is regulated by the combined effects of the concentrations of glucose in the maternal and fetal plasma and the kinetic function of the glucose transporter proteins at both the maternal- and fetal-facing trophoblast membranes.[24] There is also considerable need for more research into the regulation of placental glucose transporter expression and related placental glucose uptake, metabolism, and transport to the fetus, since there are demonstrable differences among isoform specificity, time dependency, and species, as well as the impact of changes in selective (glucose, amino acids) nutrient supplies.

Transplacental Glucose Concentration Gradient

Net transport of glucose from mother to fetus across the placenta requires a net maternal-fetal plasma glucose concentration gradient. In all species studied, including humans, the fetal plasma glucose concentration has been observed to be significantly lower than that measured in a simultaneously obtained blood sample from the mother.[25] In addition, a significant positive relationship has been observed between the prevailing glucose concentration in the mother and the fetus.[1] This nearly linear relationship between maternal and fetal glucose concentration covers the physiologic range of glycemia, but experimentally has been seen during acute hyperglycemia induced by glucose infusion to the mother and during hypoglycemia induced by insulin infusion to the mother.

Placental Glucose Consumption

The transplacental glucose concentration gradient is produced by both placental and fetal glucose consumption. The contribution by the placenta is large, as the placenta is a highly metabolically active organ. In pregnant sheep near term, for example, the placenta can consume almost twice as much glucose as the fetus, even though the placental/fetal weight ratio is only about 1:10.[26] Thus, a large part of uterine glucose uptake is consumed by placental glucose metabolism, which contributes significantly to the lower glucose concentrations of the fetus relative to the mother and helps to establish the transplacental glucose concentration gradient; without placental glucose consumption, fetal arterial glucose concentration would markedly increase. Glucose utilization in the placenta also contributes to placental glycogen formation via glycogenin.[27]

Placental Glucose Transport Kinetics

The relationship between the rate of placental glucose transfer to the fetus and the maternal-fetal plasma glucose concentration gradient is complex. Placental and fetal glucose consumption rates vary independently of each other. Furthermore, in vivo studies in pregnant sheep have shown that the glucose transporter proteins at both maternal and fetal placental membranes demonstrate saturation kinetics.[28] (Figure 27-2[28]). In these studies, glucose clamp experiments produced steady-state net fluxes of glucose into and across the placenta and into the fetus at different concentrations of glucose in the maternal and fetal circulations. Uptake and net consumption of glucose by the uteroplacenta demonstrated saturation kinetics with maximal uptake rate (V_{max}) occurring at the upper range of normal ovine maternal plasma glucose concentrations. Similar

results have been measured in a variety of in vitro perfusion experiments in human placentas, although V_{max} in the human placenta studied in vitro is severalfold higher than in pregnant sheep studied under normoglycemic conditions (to date, there are no in vitro, perfused placental studies in the ovine placenta).[29]

Summary of Placental Glucose Uptake, Consumption, and Transport

(Figure 27-3) summarizes the regulation and quantitative aspects of placental glucose uptake and transport. First, uterine, placental, and fetal glucose uptake are directly related to maternal glucose concentration (Figure 27-3), left panel).[29] Second, fetal glucose uptake is separately regulated by fetal glucose concentration by which a relatively lower glucose concentration in the fetus establishes a larger maternal-fetal glucose concentration gradient and thus increased transfer of glucose to the fetus (Figure 27-3, middle panel).[29] In contrast, at any maternal glucose concentration, placental glucose consumption is directly related to fetal arterial plasma glucose concentration (Figure 27-3), right panel).[29] In fact, the fetal side of the placenta has an eightfold greater capacity to take up glucose than the maternal side, so that changes in fetal glucose concentrations have a strong influence on placental glucose flux and metabolism.

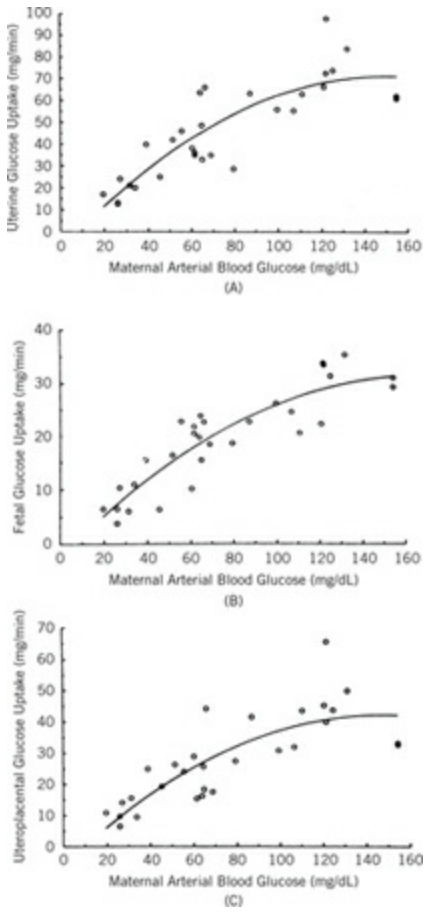

Figure 27-2 Relationship between maternal glucose concentration and the net uptake of glucose by the uterus, fetus, and uteroplacenta. Glucose was infused into pregnant sheep after an overnight fast to produce a large variety of maternal arterial blood glucose concentrations. Net glucose uptake rates by the uterus (A), fetus (B), and uteroplacenta (C) were quantified by the Fick principle. All three relationships show saturation kinetics with an approximate K_m value (a measure of the sensitivity of the transport processes to maternal glucose concentration) in the physiological range of maternal glucose concentration (about 50–60 mg/dL [2.8–3.3 mM]). These results show that maternal glucose concentration determines the entry of glucose into the uterus, uteroplacenta, and fetus. Reproduced with permission of the Society for Experimental Biology and Medicine.[28]

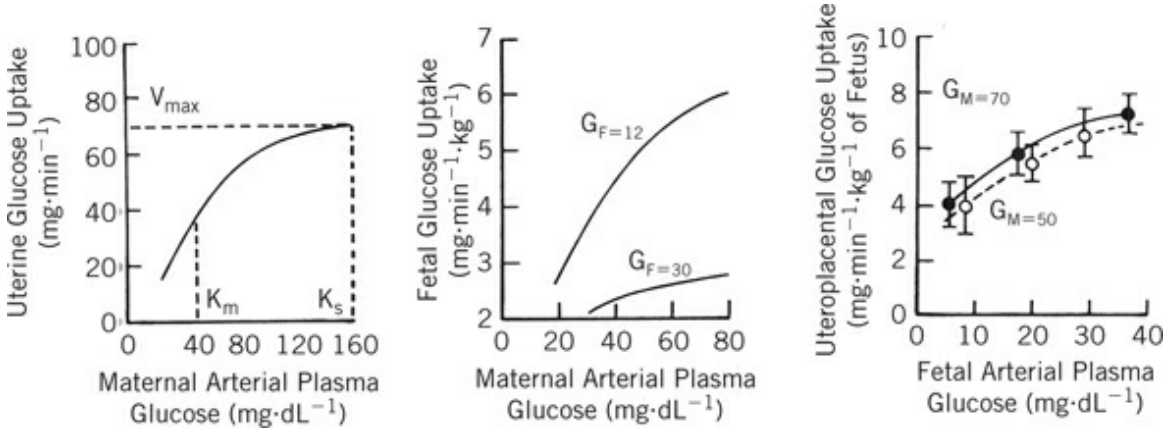

Figure 27-3 Left panel: Net rate of glucose transfer into the uterus from the maternal plasma versus maternal plasma glucose concentration. V_{max} is the maximum rate that glucose can enter the uterus; Km is one-half of V_{max} and a measure of the sensitivity of uterine glucose uptake to maternal glucose concentration; Ks is the maternal glucose concentration at which V_{max} is reached. Middle panel: Net rate of glucose transfer into the fetus from uteroplacenta versus maternal plasma glucose concentration; a lower fetal glucose concentration relative to any maternal glucose concentration produces a greater maternal-fetal glucose concentration gradient and a higher rate of placental to fetal glucose transfer (upper curve versus lower curve). Right panel: Net rate of uteroplacental glucose consumption versus fetal plasma glucose concentration; at any maternal glucose concentration (data for maternal glucose concentrations of 50 and 70 mg/dL are shown), uteroplacental glucose consumption is directly related to fetal glucose concentration. These data show that maternal glucose concentration determines the rate of glucose entry into the uterus (and thus the fetus and placenta), but the rate of uteroplacental glucose consumption is regulated by the fetal glucose concentration. Adapted from Refs. 24 and 29.

Fetal Glucose Utilization

Kinetics of Glucose Utilization in the Fetus

Placental glucose transfer to the fetus is also due to the saturation of the capacity for glucose utilization in the fetus. This capacity itself is variable, as increased fetal glucose supply from the placenta and increased fetal plasma glucose concentration act to increase fetal insulin secretion. In turn, increased fetal insulin concentration augments fetal glucose utilization and

plasma clearance, effectively limiting the increase in fetal glucose concentration as maternal glucose concentration and maternal-to-fetal glucose transfer increase.

Effects of Fetal Plasma Glucose and Insulin on Fetal Glucose Metabolism

The rate of fetal glucose metabolism (total utilization as well as the rate of fetal glucose oxidation) depends directly on the simultaneous interaction of fetal plasma glucose and insulin concentrations. An example in near-term fetal sheep depicting the effect of glucose and insulin concentrations simultaneously on fetal glucose utilization, measured as glucose oxidation to CO2, is shown in (Figure 27-4).[30] Although both glucose and insulin act independently (i.e., additively) to increase glucose utilization and oxidation in the fetus according to saturation kinetics, the relative proportion of glucose oxidized during short-term three- to four-hour studies (about 55% in fetal sheep) does not change significantly over the entire range of glucose utilized. Thus, the principal metabolic effect of insulin in the fetus is to increase the permeability of insulin-sensitive cells to glucose via increased Glut-4 translocation to cell membranes, enhancing glucose uptake and utilization in general, and oxidation of glucose in proportion to uptake and utilization, rather than to differentially affecting intracellular pathways of glucose metabolism. At least this is true on balance for the whole fetus; individual tissues and metabolic pathways may vary significantly in their responsiveness to insulin. Such a permissive role for insulin in fetal sheep might be different from the human fetus, which, like the human adult, has a greater capacity to produce fat in adipose tissue from glucose as well as fatty acids and triglycerides.

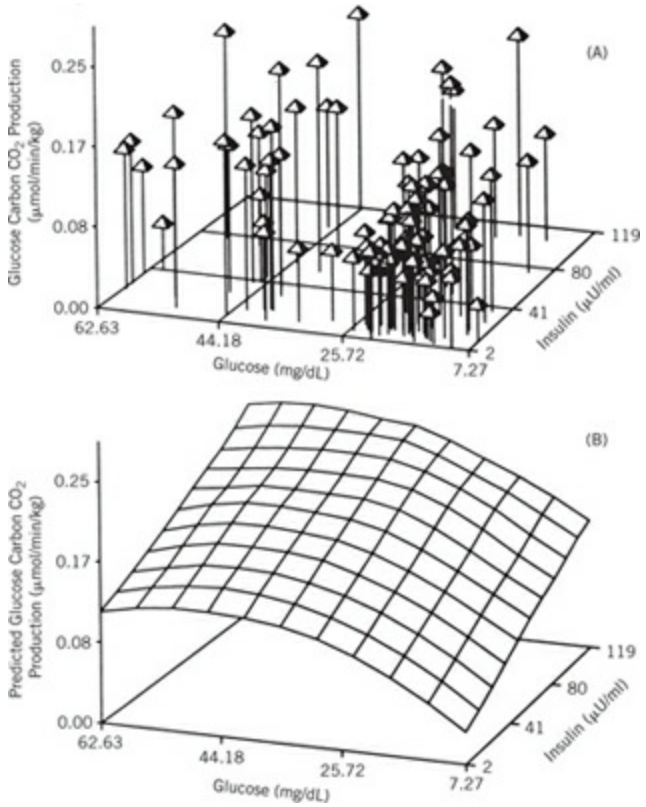

Figure 27-4 Data from fetal sheep showing the additive effects of plasma glucose and insulin concentrations on fetal glucose oxidation rate measured as CO_2 production rate. (A) Three-dimensional plot of individual values of the rate of glucose oxidation to CO_2 at different concentrations of glucose and insulin. (B) Predicted values of the rate of fetal glucose oxidation to CO_2 displayed as a three-dimensional glucose × insulin surface from the values in (A). Reproduced with permission from the American Physiological Society.[30]

Glucose Transporters and Glucose Uptake and Metabolism in the Fetus

Glucose is transported into cells in the fetus, just as in the placenta and newborn and adult, by glucose transporters. Glut-1 is the predominant fetal glucose transporter isoform and is found in abundance in most fetal tissues.[31] In contrast, tissue-specific isoforms, such as the neuronal Glut-3 in brain, Glut-2 in hepatocytes and pancreatic β-cells, and Glut-4 in insulin-responsive tissues such as skeletal muscle, heart, and adipose tissue, are expressed in low amounts in fetal tissues compared with Glut-1.[32,33]

Both acute and chronic changes in fetal glucose and insulin concentrations have been studied in fetal sheep to address the interrelationships among absolute changes in glucose and insulin concentrations, duration of change in glucose and insulin concentrations, expression of glucose transporter concentrations, and glucose utilization rates in the fetus. In chronic studies lasting two-four weeks in late gestation, sustained hyperglycemia was associated with a progressive decrease to normal or subnormal insulin concentrations.[34] Under these conditions there was a transient increase in brain Glut 1 but not Glut-3 concentrations, and a progressive decline in liver and adipose tissue Glut-1 and myocardial and skeletal muscle Glut-1 and Glut-4. Further studies showed that the chronic hyperglycemia and reduction in Glut-4 correlated with the development of insulin resistance.[35] These observations in the fetal sheep mimic results obtained in the rat fetus exposed to a maternal diabetic environment.[36] Chronic hypoglycemia (produced by maternal insulin infusion) produced a decline in brain Glut-3, an increase in brain Glut-1, and a subsequent decline in liver Glut-1, but no significant change in insulin-sensitive myocardium, skeletal muscle, or adipose tissue Glut-1 or Glut-4 concentrations. These time-dependent and tissue- and isoform-specific changes in response to altered circulating glucose and/or insulin concentrations showed that cellular adaptations in Glut-1 and Glut-3 protect the fetus from perturbations in substrate availability, and the adaptations in Glut-4 lead to the development of insulin resistance.

In acute studies, expressions of Glut-1, 3, and 4 were studied in response to increasing duration (1, 2.5, and 24 hours) of selective hyperglycemia or hyperinsulinemia.[37] Hyperglycemia initially increased fetal glucose utilization rate associated with an increase in Glut-1 and 3 isoforms that mediate basal glucose utilization, but no change in Glut-4 that mediates insulin action. Fetal glucose utilization rate subsequently returned to normal values by the end of 24 hours. These results contrast with the tissue-specific effects of selective hyperinsulinemia, which produced a sustained increase in fetal glucose utilization rate associated with a sustained increase in hepatic Glut-1 and a myocardial-specific emergence of mild insulin resistance associated with a down-regulation of Glut-4. In skeletal muscle specifically, there was a lack of sustained temporal association between the increases in transporter proteins and glucose utilization rates,[38] which indicates that subcellular localization and activity of transporter or tissues other than skeletal muscle contribute to net fetal glucose utilization rate.

These observations support an immediate but transient cellular

adaptation of augmented glucose uptake associated with a transient increase in Glut-1 concentration in response to an acute hyperglycemic perturbation in the intrauterine milieu. In contrast, alterations in the hormonal milieu (specifically of insulin) did not demonstrate any acute effects on the mechanisms underlying insulin-induced cellular glucose transport, except for a sustained increase in hepatic Glut-1 concentrations and an increase in skeletal muscle Glut-4 concentrations. Whether chronic hyperinsulinemia in the presence of hyperglycemia or euglycemia leads to adaptations of fetal ovine glucose transporter proteins toward enhancing or limiting intracellular substrate delivery remains unknown. Also unknown are the responsible mechanisms, such as Glut gene transcription or translation and posttranslational protein stability, that underlie both acute and chronic adaptation to changes in circulating glucose and insulin concentrations.

Basal Insulin Concentration

The basal concentration of insulin in the fetus probably has a role in fetal glucose utilization, but direct evidence for this is not as convincing as the effect of hyperinsulinemia. For example, an acute decrease of fetal plasma insulin concentration with somatostatin infusion does not appear to affect fetal glucose concentration or glucose utilization.[39] In contrast, a chronic selective decrease of fetal plasma insulin concentration, for example, by fetal pancreatectomy or streptozotocin injection into the fetus, reduces fetal growth and decreases umbilical glucose uptake in relation to fetal hyperglycemia. The hyperglycemia results from decreased peripheral tissue insulin sensitivity and glucose utilization and from the release of insulin's normal inhibition of hepatic glucose production.[7]

Interaction Between Glucose and Alternative Carbon Substrates for Fetal Oxidative Metabolism

At markedly reduced rates of glucose supply to the fetus, fetal glucose utilization rate decreases proportionally.[29] Under such short-term conditions, fetal oxygen consumption remains near normal,[29] indicating active reciprocal oxidation of other substrates, at least over the short term, such as glucose released from glycogen, lactate, amino acids, fatty acids, and ketoacids. Over longer periods (more than three weeks) of reduced glucose supply, fetal oxygen consumption tends to decrease by 25%–30%; because the rate of fetal growth decreases at the same time and to the same extent as the decrease in oxygen consumption, the reduction in fetal oxygen consumption probably represents the oxidative requirements of the

decreased protein synthetic activity.[40] Furthermore, when exogenous amino acids are infused into the fetal sheep, the glucose/oxygen quotient and glucose uptake rate decrease and leucine oxidation increases, further supporting fetal substrate switching, perhaps coupled with decreased placental glucose transport to the fetus.[41]

Fetal Glucose Utilization Rates

Quantitative aspects of fetal glucose utilization have been made in several large animal models. In most studies, fetal glucose utilization rate is about 5 mg/min/kg fetal weight near term, about half of values in mid-gestation when fetal growth and metabolic rate are also as much as twice as great as they are closer to term.[42] In humans, based on the increase in total maternal glucose production in late gestation, fetoplacental glucose utilization is estimated to be about 5–6 mg/min/kg fetal weight.[11] This rate is similar to that measured in normal term infants.[43] Table 27-2 presents estimated utilization rates of glucose in several fetal organs and the remaining carcass of fetal sheep in late gestation. The fraction of glucose oxidized versus the fraction entering tissue accretion pathways in these organs has not been determined, and the factors that regulate glucose uptake in specific organs remains poorly studied. Most organs appear dependent on plasma glucose concentration for their specific rate of glucose uptake, and certain organs such as skeletal muscle and probably the heart and liver are insulin sensitive (at least in sheep studied in vivo).

TABLE 27-2 Metabolic Rates in the Fetus That Account for Glucose Utilization (Based on Data in Fetal Sheep and Estimates for Human Fetuses for Brain)

	Glucose Utilization Rate (mg/min/kg fetus)	Percent of Total
Whole fetus (sheep, measured)	5.0	100
Whole fetus (human, estimated)	6.0-8.0	100
Brain (sheep, measured)	0.8	16
Brain (human, estimated)	4.0	50–67
Heart (sheep, measured)	0.65	13
Lungs (sheep, estimated)	0.1	2
Liver (sheep, measured)	0.1	2

Red blood cells (human, estimated)	0.1	2
Gut (sheep, estimated)	unknown	unknown
Carcass/skeletal muscle (sheep, estimated)	3.25	65
Total of organs accounted for:		
Sheep	5.0	100
Human	8.2	103–137

Gestational Development of Placental Glucose Transport and Fetal Glucose Utilization

The fetus grows severalfold in size over the second half of gestation, as does its absolute rate of glucose utilization. Placental glucose transfer to the fetus, therefore, must increase to meet the increasing metabolic requirements for glucose of the larger, growing fetus. The increase in placental glucose transport occurs for two reasons: (1) the transplacental glucose concentration gradient increases as the fetal glucose concentration decreases relative to maternal glucose concentration (Figure 27-5, top panel); (2) the placental transport capacity itself increases (Figure 27-5, middle panel).[42]

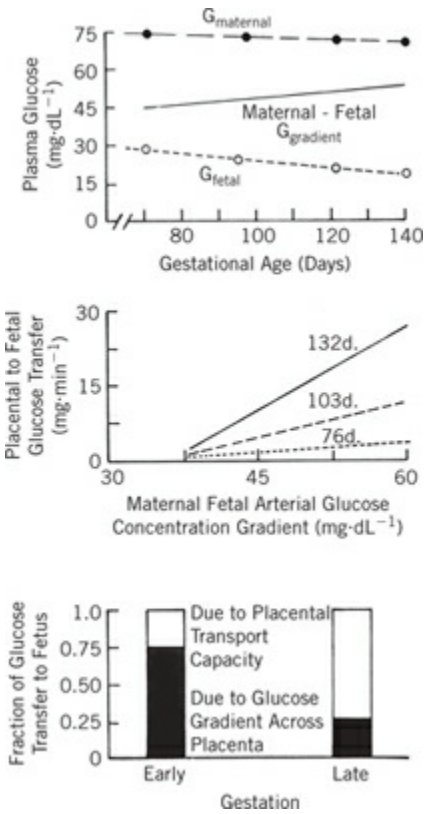

Figure 27-5 Upper panel: Plasma glucose concentration tends to decrease in fetal sheep (–O–) over the second half of gestation relative to the maternal plasma glucose concentration (–•–). This increases the maternal-fetal plasma glucose concentration gradient or the driving force for transplacental glucose transfer (—). Middle panel: Placental-to-fetal glucose transfer (PGT) increases about eightfold over this same period. This increase in transport largely reflects transport capacity, shown by the increasing slope of PGT as gestational age increases. Bottom panel: At mid-gestation, most of PGT is due to the maternal-fetal glucose concentration gradient, whereas by term, the placental transport capacity for glucose accounts for most of PGT. Adapted from Ref. 42.

Placental glucose transport capacity develops primarily by an increase in the total amount rather than the affinity of the glucose transporters.[44] The number of glucose transporter proteins can increase by an increase in the trophoblast membrane surface area, an increase in the concentration of transporters per unit membrane area, or both. There is some evidence from in vitro studies that maternal and fetal glucose concentrations can regulate placental glucose transporter expression, either directly or through IGF-I action.[45] By late gestation, glucose transport capacity by the placenta has a dominant role in the regulation of glucose transport to the fetus (Figure 27-5, bottom panel[42]).

Fetal glucose concentration may decrease relative to maternal glucose concentration over the second half of gestation for several reasons. First, fetal cellularity increases over this period, as does the fraction of body weight that consists of insulin sensitive tissues (e.g., skeletal muscle and adipose tissue).[46] Second, fetal insulin concentration increases, developmentally and in response to glucose and other secretagogues.[47] Third, insulin-sensitive Glut-4 transporters on fetal skeletal muscle and adipose tissue cell membranes also increase over gestation, at least due to the increase in the relative body content of these insulin-sensitive tissues. The result is an increase in the effectiveness of insulin to promote fetal glucose utilization and glucose clearance, thereby reducing the relative fetal plasma glucose concentration. On balance, however, by late gestation, the increasing gradient of glucose concentration across the placenta contributes only limited control over placental transport of glucose to the fetus.

Fetal Insulin Secretion

Many studies have addressed the onset and development of insulin secretion from the fetal pancreas. The fetal pancreas develops in the late first to early second trimester, producing measurable insulin concentrations by mid-gestation. As noted earlier, there is a gradual increase in basal insulin concentration and glucose- and arginine-stimulated insulin secretion toward term.[47] In the rat, very little insulin is secreted in the fetus,[48] while in the human fetus, which normally does not secrete much insulin,[49] sustained hyperglycemia in pregnant diabetics,[50] particularly when the hyperglycemia is pulsatile, produces considerable insulin. Fetal sheep are somewhere in between, showing down-regulation of glucose-induced and basal insulin secretion in the presence of chronic, sustained, marked hyperglycemia as with the rat, but increased insulin secretion with pulsatile hyperglycemia as in humans.[51] Hypoglycemia decreases basal and glucose-induced insulin secretion,[52] perhaps a fundamental aspect of how IUGR with fetal hypoglycemia decreases fetal pancreatic development and insulin secretion capacity. Clearly fetal insulin secretion responds variably to changes in glucose concentration that are dependent on the absolute change in glucose concentration, its magnitude, and its pattern.

Alternate Carbohydrates Produced in the Placenta

The placenta also contributes to fetal carbon supply by metabolizing glucose to lactate (in most or all species) and fructose (in ruminants).[1] Lactate produced in the placenta enters both maternal and fetal circulations at about equal rates under normal conditions, whereas fructose produced in the placenta only enters the fetal circulation. At normal rates of lactate and fructose uptake by the fetus and their oxidation fractions in fetal tissues measured in late-gestation pregnant sheep, these two substrates could supply carbon sufficient to account for another 20%–30% of the carbon requirements for fetal oxygen consumption above that provided by glucose.

Adaptations to Changes in Glucose Supply

Hypoglycemia (Table 27-3)

TABLE 27-3 Fetal Responses to Decreased Glucose

Supply and Hypoglycemia
Acute
Decreased glucose uptake
Decreased insulin production and secretion
Hypoinsulinemia
Decreased glucose utilization
Increase in the rate of placental glucose transfer to the fetus as fetal hypoglycemia tends to increase the maternal–fetal glucose concentration gradient
Decreased placental lactate production
Decreased fetal lactate uptake and utilization
Substitution of other substrates to main oxidative metabolism
Chronic
Initial increase in fetal glucose production, then a return toward the normal condition of little or no fetal glucose production
Initial increase in amino acid oxidation, then a return to normal rates
Decreased insulin sensitivity
Increased ratio of fetal to maternal glucose concentration
Increased ratio of placental glucose consumption to placental glucose transfer

Short-term maternal hypoglycemia has been studied in the late-gestation pregnant sheep.[53] As shown in Figure 27-6,[53] several days of fasting-induced hypoglycemia produce proportional reductions in glucose uptake by maternal nonuterine tissues, the fetus, and the uteroplacenta. Similar changes in glucose utilization by these tissues have been found with acute, several hour insulin-induced hypoglycemia.[29] At the same time, however, uteroplacental oxygen consumption rate does not change. Thus, even with hypoglycemic conditions, other substrates must substitute for glucose to maintain oxidative metabolism. As glucose utilization by the placenta is decreased, however, so is uteroplacental production of lactate (and fructose in sheep). There is little or no change in placental utilization of free fatty acids (FFAs), ketoacids, or amino acids. Thus, uteroplacental oxygen consumption can be maintained by a balance in which a decreased supply of glucose to the fetus also results in a decreased production of exported products of glucose metabolism, allowing glucose carbon to be used preferentially for oxidative metabolism.

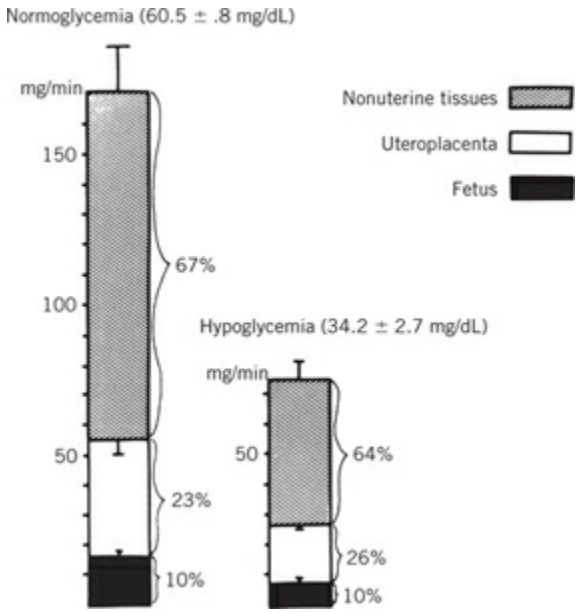

Figure 27-6 Fractional partition of maternal glucose production to nonuterine maternal tissues, uteroplacenta, and fetus in normoglycemic sheep (first column) and hypoglycemic sheep (second column) showing that in short term, there is no change in the relative proportions of glucose used by these three sets of tissues. Thus, fetal and placental glucose needs are dependent on the supply of glucose from the maternal plasma glucose pool; with longer term maternal glucose deficiency, either the fetus must use its own sources of glucose (glycogenolysis or gluconeogenesis) or rely on other substrates such as amino acids for carbon balance. Reproduced with permission from the American Physiological Society.[53]

This pattern is maintained with much longer periods of hypoglycemia, but two other adaptations develop under chronic conditions as well. First, fetal gluconeogenic gene expresion and glucose production develop.[7,41] These increase the fetal glucose concentration relative to that of the mother and shift the balance of glucose uptake by the uterus more to placental glucose consumption and less glucose transfer to the fetus (see (Figure 27-1). Fetal glucose production thus serves two purposes: (1) the maintenance of fetal glucose metabolism, and (2) the diversion of diminished glucose supply to the uterus into placental metabolism. Fetal glucose production, therefore, maintains the glucose metabolic requirements of the fetus and placenta without further drain on the diminished availability of glucose in the mother; this may represent a simple “survival” adaptation. If persistent

in neonatal and postnatal periods, however, this adaptation could have adverse consequences by promoting glucose production in excess of the capacity for glucose utilization, contributing to persistent hyperglycemia, a hallmark of type 2 diabetes.

Gluconeogenesis is regulated such that expression of PEPCK, glucose-6-phosphatase, and fructose-1, 6-bisphosphatase are normally quiescent until just prior to birth when increases in glucagon, cortisol, and catecholamines activate the glycogenolytic and gluconeogenic pathways.[54] Experiments in fetal sheep indicate similar effects of these hormones on glucose metabolism.[6,9,54,55] Insulin is the primary hormone responsible for suppression of hepatic glucose production and gluconeogenic gene expression and activation of glycolysis and lipogenesis. In the fetal sheep exposed to hypoglycemia, concentrations of the counter-regulatory hormones, cortisol, glucagon, and norepinephrine are increased, while insulin concentrations are reduced, producing a hormonal combination (e.g., decreased ratio of insulin to counter-regulatory hormones) favoring gluconeogenesis.[56,57] Importantly, an increase in circulating insulin concentration is able to suppress fetal glucose production and gluconeogenic gene expression that are induced by hypoglycemia. Insulin also increases fetal glucose utilization rates and expression of hepatic glycolytic and lipogenic genes, indicating maintained hepatic insulin action.[57]

The second adaptation to chronic hypoglycemia in late gestation is a reduction in placental and fetal growth rates, resulting in lower fetal and placental weights.[40,58] Because placental glucose transfer capacity does not change at the same time, placental weight reduction, or failure to maintain weight, does not appear to include a reduction in placental membrane surface area or glucose transporter number or affinity. This provides additional evidence that with chronic hypoglycemia and decreased placental glucose supply, placental glucose carbon is shunted to oxidative metabolism. It is interesting to speculate that all these take place to substitute reduced rates of fetal and placental growth for reduced substrate supply, maintaining normal fetal and placental tissue-specific rates of metabolism, and preserving their function and viability without further demands on maternal metabolism.

Intrauterine Growth Restriction

IUGR is a unique example of how fetal glucose metabolism and its regulatory mechanisms adapt to glucose deficiency and hypoglycemia to maintain normal fetal glucose metabolism. Regardless of the model, when

the fetus is deprived of glucose by placental insufficiency or maternal hypoglycemia, fetal weight-specific glucose utilization rate is not very much different from normal rates.[6,7,59] This indicates that one of the mechanisms to enhance glucose uptake by the fetus from the placenta is the production of further hypoglycemia, thereby increasing the maternal-fetal glucose concentration gradient. To do this, there must be an increase in the fetal tissue capacity for glucose uptake and/or utilization. This could come about by increased concentrations and/or activity and/or plasma membrane localization of glucose transporters, increased insulin signal transduction and thereby effectiveness to promote Glut-4 (and perhaps Glut-1) translocation to the cell membrane, or mechanisms of insulin metabolism into oxidative and/or nonoxidative pathways. In both fetal sheep and fetal rats with IUGR, Glut-1 and Glut-4 concentrations in the brain, liver, myocardium, adipose tissue, and skeletal muscle do not decrease with sustained hypoglycemia,[6,31,32,60] perhaps a positive adaptation to maintain glucose utilization despite hypoglycemia. It has not been determined whether this maintenance of glucose transporter concentration is sufficient by itself to maintain the glucose utilization at normal rates. Future studies are necessary to sort out this fascinating and complex adaptation to glucose deficiency among the many tissues in the fetus. Recent studies in late-gestation IUGR fetal sheep show maintained or even increased weight-specific rates of glucose utilization during hyperinsulinemic clamps, indicating increased insulin sensitivity for peripheral glucose disposal.[7,61,62]

Recent data have shown increased fetal hepatic gluconeogenic gene expression and glucose production rates in a variety of conditions that limit nutrient supply to the fetus, including the nutrient-restricted fetal baboon, hypoglycemic fetal sheep, IUGR fetal sheep liver produced from placental insufficiency (PI-IUGR), and IUGR neonatal rodents.[6,7,63–66] Understanding these fetal adaptations is important, as persistence of these fetal phenotypes into postnatal life likely contributes to the increased risk for development of uncontrolled hepatic glucose production, hepatic insulin resistance, and type 2 diabetes.[67]

As mentioned earlier, hepatic insulin action is maintained in the hypoglycemic fetus. This is in contrast to the PI-IUGR fetus that develops hepatic resistance to insulin-mediated suppression of gluconeogenic gene expression and glucose production,[7] indicating that factors other than fetal hypoglycemia in IUGR lead to hepatic insulin resistance. PI-IUGR and hypoglycemic fetuses have increased hepatic phosphorylation of cAMP

response element-binding protein and peroxisome proliferator-activated receptor gamma co-activator (*PGC1γ*) gene expression, supporting the concept that increased counter- regulatory hormone-mediated cAMP activation may drive activation of glucose production.[6,55,66] One of the major differences between the hypoglycemic and PI-IUGR models is fetal oxygenation status. Oxygenation is normal in the hypoglycemic fetus, in contrast to the PI-IUGR fetal sheep, which can have up to a ~50% reduction in fetal arterial blood oxygen content and PO_2. Despite these differences, both hypoglycemic and PI-IUGR fetuses have similar oxygen consumption rates.[65,68–70] Thus, lower oxygen values may have an effect on glucose production and insulin sensitivity in the PI-IUGR fetus rather than on the metabolic rate of oxygen consumption. Future studies are needed to measure the effect of chronic insulin infusion on umbilical venous and arterial oxygenation, umbilical blood flow, and net fetal oxygen consumption rates.

Lactate concentrations and umbilical uptake rates are similar between normal and hypoglycemic fetuses.[68] In contrast, the PI-IUGR fetus has higher lactate concentrations, raising the possibility that lactate might drive glucose production in the PI-IUGR model but not the hypoglycemic model.[7,65,66] Hepatic glycogen content is also similar between normal, hypoglycemic, and PI-IUGR fetuses, supporting gluconeogenesis rather than glycogenolysis as the source of hepatic glucose production when glucose supply is chronically reduced.[7,65,66]

Hyperglycemia (Table 27-4)

TABLE 27-4 Fetal Responses to Increased Glucose Supply and Hyperglycemia

Acute: Mild-moderate
Increased glucose uptake
Increased insulin production and secretion
Hyperinsulinemia
Increased glucose utilization
Increased fetal oxygen consumption
Mild arterial hypoxemia
Respiratory acidosis
Increased placental lactate production
Increased fetal lactate uptake and utilization

Acute: Severe
Arterial hypoxemia
Hypoinsulinemia
Increased erythropoietin
Increased fetal oxygen consumption
Metabolic acidosis
Decreased placental perfusion
Fetal demise
Chronic
Decreased insulin secretion and/or synthesis
Decreased peripheral insulin sensitivity
Increased ratio of placental glucose consumption to placental glucose transfer

Acute maternal hyperglycemia produces an increase in uteroplacental glucose uptake with saturation kinetics that parallel those of the fetus. At the same time, uteroplacental oxygen consumption rate does not change[29]; thus, increasing amounts of glucose consumed by the placenta are shunted into nonoxidative pathways. These include increased rates of lactate and fructose production, as well as increased use of glucose carbon for placental tissue, particularly glycogen.

With chronic hyperglycemia in the mother, produced by glucose infusion or experimental diabetes, similar patterns of glucose metabolism in the placenta have been observed. Fetal adaptations produce other changes as well. For example, chronic fetal hyperglycemia in experimental animals, in response to chronic, relatively constant and marked maternal hyperglycemia, eventually appears to down-regulate fetal pancreatic insulin secretion and causes pancreatic β-cell apoptosis.[71] This affects the basal rate of insulin secretion and also appears to later decrease the secretion of insulin in response to acute hyperglycemia.[72] As a result of hypoinsulinemia in the presence of hyperglycemia, fetal hyperglycemia is exaggerated, shifting the increased rate of uterine glucose uptake more into uteroplacental glucose consumption. Oxidative metabolism, measured as the uteroplacental rate of oxygen consumption, still does not change. Thus, uteroplacental glucose metabolism increasingly enters nonoxidative pathways. The particular metabolic pathways of glucose carbon under these conditions have not been explored. Placental size is not dramatically increased, suggesting that export of placental glucose carbon into lactate and fructose and perhaps other products accounts for the balance of glucose carbon not used for oxidative metabolism. Of course, glucose

carbon could substitute for the oxidation of carbon normally provided by other substrates, including ketoacids and fatty acids, but principally the amino acids. Normally, the glucose oxidation fraction in the placenta of sheep in late gestation, corrected for lactate carbon and fructose carbon export, is still only about 50%. Thus, half of placental oxidative metabolism must be supplied by other substrates. Some amino acids such as leucine and serine may be oxidized within the placenta directly as they are taken up from the maternal plasma and concentrated within the trophoblast cytosol. In contrast, glutamate is produced in the fetal liver from glutamine and then taken up by the placenta where as much as 70%–80% is oxidized.[73] It is certainly possible, therefore, that under hyperglycemic conditions, excess glucose carbon could substitute for carbon that is derived from amino acids, ketoacids, and fatty acids under normoglycemic conditions. Thus, there are clear interrelationships among a variety of carbon substrates that can act as sources of carbon for placental oxidative metabolism, and these interrelationships appear to be regulated by placental glucose supply.

LIPIDS

Placental Lipid Uptake, Metabolism, and Transfer to the Fetus

Less is known about human placental lipid uptake, metabolism, and transfer to the fetus than is known for glucose, principally because most experimental animal models, especially the sheep, demonstrate little capacity for lipid uptake, metabolism, and transport by the placenta. Also, lipid transport by the human placenta has not been studied in vivo, and there is large variation in the data obtained from human placental tissue studied in vitro. Even so, the human placenta appears to have considerable capacity for lipid transfer. Transporters for specific fatty acids, especially the long-chain polyunsaturated fatty acids (LCPUFAs), docosahexaenoic acid (DHA: 22:6 ω-3) important for structural integrity of membranes, and arachidonic acid (AA: 20:4 ω-6) important for neural and retinal development, are primarily involved. More complex pathways include lipoprotein dissociation by placental lipoprotein lipase (LPL) activity (although the exact cellular source of LPL in the placenta remains in question), triglyceride uptake and metabolism (including metabolic pathways of oxidation, chain-lengthening, synthesis, and interconversion pathways), and release into the fetal plasma as FFAs or lipoproteins.

Recent reviews summarize information about placental lipid transport and fetal lipid metabolism and accumulation.[74–76]

Importance of Placental Lipid Metabolism to Fetal Lipid Supply

The amount and type of fatty acid or complex lipid transported by the placenta varies among species-greatest in the hemochorial placenta of the human, guinea pig, and rabbit, and least in the epitheliochorial placenta of the ruminant and the endotheliochorial placenta of the carnivores. Furthermore, it is interesting that fetal fat content at term among species varies reasonably directly with the lipid transport capacity of the placenta.[77] There are many lipid substances in the plasma that are transported across the placenta, which are essential for placental and fetal development even if they do not contribute to nutritional or energy metabolism. Also, brown fat is common to all fetuses; it is essential for postnatal thermogenesis, even if the neonate is not "fat" with white adipose tissue. Furthermore, many lipid substances entering the fetus are qualitatively different from those taken up by the uterus and uteroplacenta, implying active placental metabolism of individual lipid substances. Placental lipid metabolism, therefore, is qualitatively as well as, in some cases, quantitatively important for fetal development and growth, even if the fetus does not get very fat.

Placental Uptake, Synthesis, Metabolism, and Hydrolysis of Fatty Acids

A schema of lipid uptake, metabolism, and transport in the human placenta is shown in Figure 27-7[77] After entering the placenta, fatty acids may be used for triglyceride synthesis, cholesterol esterification, membrane biosynthesis, direct transfer to the fetus, or oxidation. The most important factor that regulates the flux of lipid into the placenta and into the various pathways of transport and metabolism is the concentration of maternal plasma lipids, including FFAs and triglycerides. For example, placental triglyceride content increases in women who are fasting, who deliver preterm infants, or who have diabetes mellitus– all conditions in which maternal plasma FFA concentrations are increased.[78]

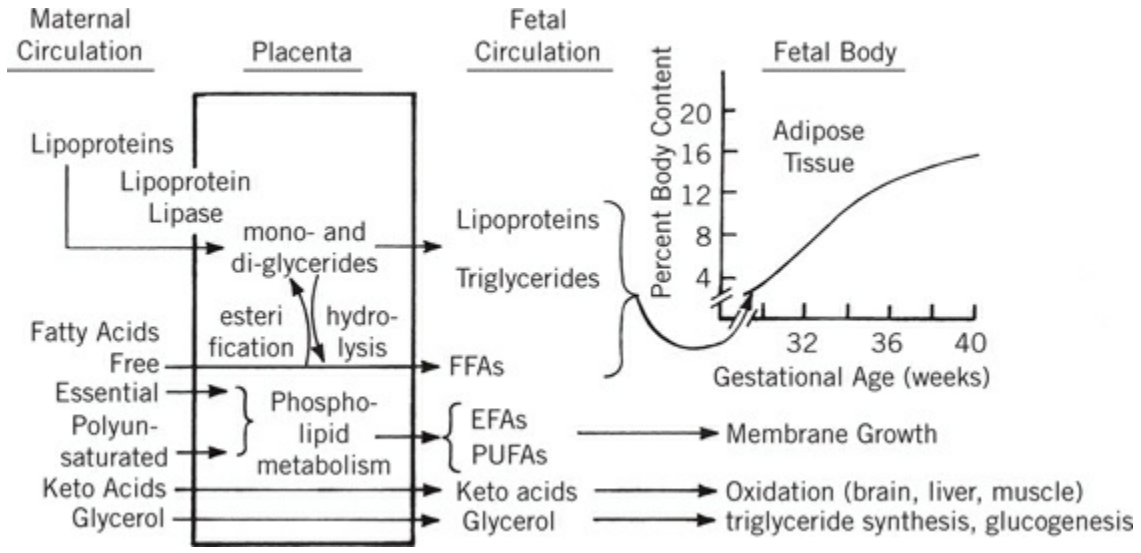

Figure 27-7 Schematic of placental–fetal interrelationships in humans for various aspects of placental lipid metabolism, fetal lipid uptake and metabolism, and fetal lipogenesis into adipose tissue. Adapted from Ref. 77.

Placental tissue from different species has been shown to express LPL activity as well as phospholipase A_2.[79,80] Maternal plasma triglycerides are hydrolyzed by these enzymes, and the released fatty acids are then taken up by the placenta. In the trophoblast cells, the fatty acids are then re-esterified and further hydrolyzed, facilitating their diffusion into the fetal circulation.

All FFAs cross lipid bilayers such as those in the syncytiotrophoblast by diffusion. Partition studies in pure phospholipid bilayers indicate that this diffusion is rapid, on the order of 20–30 milliseconds.[81] In addition, FFA transport across membranes is facilitated by fatty acid–binding proteins (FABPs), which aid in intracellular channeling of FFAs.[82] The main membrane-associated FABPs are the plasma membrane fatty acid–binding protein (FABPpm) and the FFA transfer proteins (FAT/CD36 and FATP). These transfer proteins have been found on both the maternal facing microvillous and the fetal facing basal membranes of the placental trophoblast, while a placenta-specific protein, p-FABPpm, has been found exclusively on the microvillous membrane.[83] p-FABPpm has a unique amino acid composition that enhances the binding affinity and capacity of this protein for AA and DHA compared with linolenic acid (LA) and oleic acids. The syncytiotrophoblast also contains cytoplasmic-binding proteins,

which appear to act by removing FFAs from the inner membrane and channeling them to their respective metabolic fates.[84]

Fatty acid transport into the fetal circulation is largely determined by the transplacental gradient of FFAs relative to available circulating binding protein concentrations and the activity and availability of their binding sites. In humans, fetal patterns of essential fatty acids and structural lipids correlate directly with the fatty acid/lipid composition of the maternal plasma (and, indirectly, the maternal diet).[74-76] The concentration of FFAs in the maternal plasma at term is about three times that in the fetal circulation, but the concentration of albumin, the primary carrier protein for FFAs is actually 10%–20% higher in the fetal than the maternal circulation.[85] Thus, the ratio of plasma FFAs to albumin on the fetal side of the placenta (0.3) is about 25% of that on the maternal side at term (1.3). The higher concentration of FFAs relative to available binding sites on albumin, α-fetoprotein, and other lipoproteins in the maternal compared to the fetal plasma is reflected in the concentration of unbound FFAs, which is greater in the maternal (12 nM) than in the fetal (9 nM) circulation.[86] Human cordocentesis data from 18 to 36 weeks indicates an exponential decrease in the concentration of FFAs in the fetal circulation over this period,[87] presumably because of increasing use of fatty acids in the fetus for rapidly growing structures like the brain and adipose tissue.

Although most fatty acids appear to be transported by diffusion and direct carrier-mediated mechanisms, some studies suggest that chain-altering metabolism in intratrophoblast peroxisomes may lead to a greater transfer of medium-chain fatty acids into the fetal circulation. This might be advantageous to fetal lipid metabolism, which appears to be limited in its capacity for oxidation of long-chain fats, an apparent result of low cytosolic and/or mitochondrial carnitine concentrations.[88] Fatty acids also may be esterified to di- and triglycerides and to phospholipids. These may be stored transiently or for the long term, or hydrolyzed by phospholipases and acylglycerol lipases to release fatty acids into the fetal circulation.

Additional evidence for the hypothesis that transient placental esterification of fatty acids occurs during transport of fatty acid by the placenta comes from measurements of activities of enzymes required for the isolation of glycerol-3-phosphate.[89] Such enzymes are located in the endoplasmic reticulum and have been identified in placental trophoblast cells. Although enzymatic specific activity and total enzyme content do not necessarily reflect metabolic flux, the presence of these enzymes indicates that fatty acid esterification followed by hydrolysis is a

reasonable hypothetical pathway for placental lipid metabolism and transport.

Fatty Acid and Triglyceride Synthesis in the Placenta

Fatty acids are also synthesized in the placenta. Significant fatty acid synthesis has been measured in placental tissue and cultured trophoblast cells from human,[90] sheep,[91] and pig placentas.[92] Primarily long-chain fatty acids (oleic, palmitic, and palmitoleic acids) are formed. Regarding triglycerides, radiolabeled palmitate can be incorporated rapidly into triglycerides in human placental slices, and studies of human trophoblast cells in culture have shown that incubation with albumin-bound ^{14}C-oleate produces ^{14}C-labeled cellular triglycerides. Similar observations have been made in 21-day pregnant rats studied in vivo, showing incorporation of ^{14}C-palmitate into placental triglycerides and phospholipids.[93]

Lipoprotein Synthesis in the Placenta

There is conflicting evidence regarding the synthesis of lipoproteins by placental tissue and their use for transport of fatty acids to the fetal circulation. By day 21 of gestation in the rat, the placenta appears to synthesize apoprotein B, which normally is an integral part of the major plasma lipoprotein carriers of triglycerides.[94] Such observations have not been made in the human placenta, which may secrete lipoproteins only during the early part of gestation, if at all.[95] Small amounts of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) have been identified in human amniotic fluid, but their source has not been determined.

Cholesterol Metabolism and Transfer by the Placenta

LDL cholesterol is taken up by endocytosis into trophoblast cells and degraded by lysozymes. LDL cholesterol appears to be the major precursor for placental production of progesterone and estrogen. high-density lipoprotein cholesterol also contributes to placental progesterone production in cultured human trophoblast cells. Some of this cholesterol is transferred directly to the fetus, although the role of this transport is uncertain, given the large capacity and rate of cholesterol synthesis in the fetal liver.[96]

In the fetal plasma, the fatty acids are bound to albumin and α-fetoprotein and transported to the liver where they are synthesized into triglycerides and released into the fetal circulation.[97] Since maternal

triglyceride concentration determines the activity of placental LPL and fatty acid transport across the placenta is concentration dependent, there is a direct relationship between maternal and fetal plasma triglyceride concentrations, even though there is no direct uptake and transfer of intact triglycerides by the placenta.

The fetal impact of maternal plasma FFA and lipid concentrations is also reflected in fetal lipid content and adipose tissue development.[97] Fatter human fetuses develop in pregnant women who have higher plasma concentrations of fatty acids and other lipids.[98,99] Experimentally, diabetic rats (induced by streptozotocin) have increased FFAs, and their fetuses have carcass and hepatic lipid contents that are increased twofold above normal. Similarly, rabbits fed oil–rich diets show increased neonatal adipose stores. In humans, umbilical venous-arterial fatty acid concentration differences in cord blood samples show that the net flux of FFAs into the fetus from the maternal circulation can account for the fetal requirement of fatty acids during the end of pregnancy. In contrast, the perfused human placenta may transfer fatty acids at a rate that can account for only about 20% of that required for the accumulation of fetal adipose tissue deposited during the third trimester. Other estimates, based on fetal lipid accumulation as well as in vitro transfer experiments, estimate that as much as 50% of fetal fatty acid requirements are transferred across the human placenta[75]; similar estimates have been made in the rat using the incorporation of ^{3}H from $^{3}H_2O$ into fatty acids, indicating that fatty acids are derived about equally from the mother and from fetal fatty acid synthesis. Estimates in the rabbit and the monkey indicate that in these species, placental fatty acid transfer across the placenta could account for all of fetal fat deposition in late gestation. Overall, therefore, it appears that there is a general relationship between the permeability of the placenta to lipids, especially FFAs, and the adiposity of the fetus at term, with human fetuses developing the most fat (15%–18% of body weight at term), guinea pigs second at about 12%, and rabbits third at about 7% (Figure 27-8).[99]

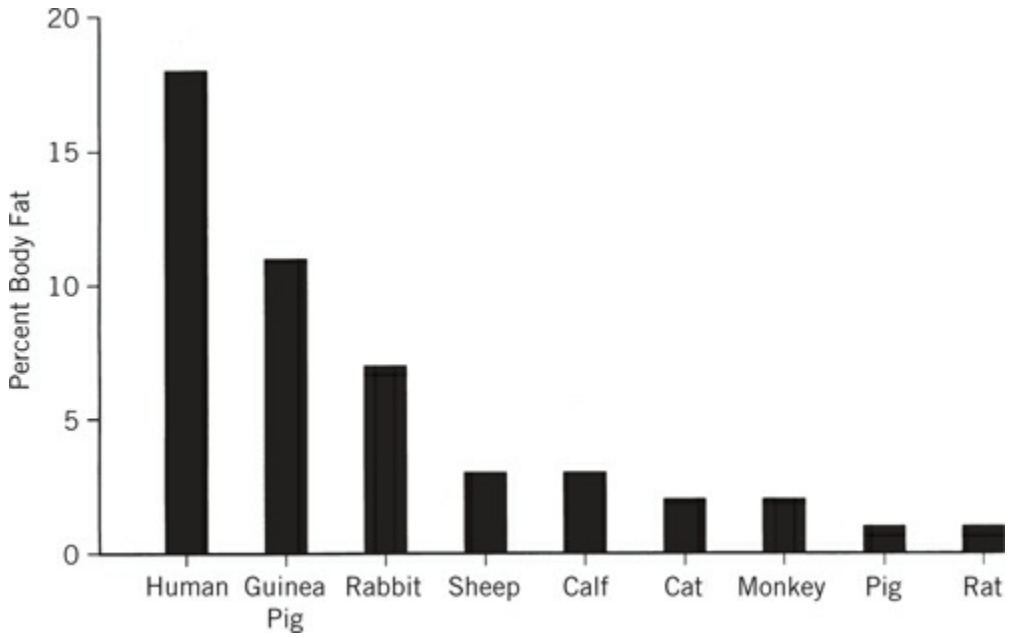

Figure 27-8 Fetal fat content at term as a percent of fetal body weight among species. Adapted from Refs. 1, 3, 77, and 99.

Availability of Essential Fatty Acids to the Fetus

Essential Fatty Acid Metabolism and Transfer by the Placenta

Essential fatty acids are readily transferred to the fetal plasma in all species studied so far. The supply of essential FFAs and especially the LCPUFAs is critical and central to the synthesis of structural lipids and, hence, to normal development of the fetus. LA (18:2, ω-6) and LA (18:3, ω-3) are the only fatty acids known to be essential for complete nutrition and must be supplied in the diet. All of the ω-6 and ω-3 fatty acid structures acquired by the fetus must, therefore, come from the mother via the placenta, either in the form of these two essential fatty acids or their LCPUFA derivatives of which AA (20:4, ω-6) and DHA (22:6, ω-3) are metabolically the most important.[100]

The preference for human placental transfer from the maternal to the fetal circulation has been reported to be docosahexaenoic>α-linolenic>linoleic>oleic>AA.[101,102] However, AA has the highest accumulation of all these fatty acids in the placenta.[103] AA uptake by placental syncytiotrophoblast membranes is highly dependent on ATP and sodium,[104] implying an active transport mechanism for this fatty acid.

Selective LCPUFA placental transfer also is due to trophoblast cellular metabolism; for example, a certain proportion of AA is converted to prostaglandins in the placenta.[101] Concentrations of AA and DHA are three to four times greater in the intervillous space of the placenta than in maternal blood, likely the result of selective LCPUFA lipase activity.[83] Also a selective incorporation of certain fatty acids into phospholipids has been found in the ovine placenta, and selective trophoblast fatty acid oxidation and lipid synthesis have been reported.[81,105,106]

Cultured trophoblast cells incubated with ^{14}C-acetate do not label AA, however, and Δ-5 and Δ-6 desaturase activities in human placental microsomes are absent at least early in gestation,[107] consistent with the absence of measurable conversion of γ-A to AA. This emphasizes the requirement for direct transfer of the essential LCPUFAs to the fetus from the maternal plasma. In fact, higher concentrations of these LCPUFAs are found in the fetus compared with the mother. These results suggest that fetal AA is either transferred directly from the mother or has a higher binding capacity in the fetal plasma, but does not exclude the possibility that some might be synthesized from LA in the fetal liver. Although the formation of AA acid and DHA from essential fatty acid precursors has been shown in term and preterm infants,[108] the degree to which the fetus is capable of fatty acid desaturation and elongation is not clear. Fetal baboons can synthesize both DHA and AA from their precursors, γ-LA and LA, respectively.[109] A low enzymatic activity of ω-5 desaturation has been proposed as one factor limiting AA synthesis,[110] and although high Δ-5 and Δ-6 desaturase activities in the liver of one 18-week and two 22-week fetuses have been reported,[103] which were close to those found in adult liver, human fetal liver desaturase-elongase chain reactions have not been clearly demonstrated in physiological conditions.

Maternal Diet and Essential Fatty Acid Supply to the Fetus

In general, reduced maternal essential fatty acid nutrition has been correlated with reduced neonatal growth and head circumference in humans.[110] Significant linear correlations between the mother and fetus or newborn have been found for both LCPUFA and essential fatty acids in healthy women eating normal, unsupplemented diets.[111] Parallel increases in plasma DHA in the mothers and newborns also have been found after fish oil supplementation during pregnancy.[112] These observations show the importance of maternal dietary fatty acids to regulate the availability of LCPUFA to the fetus and newborn. In fact, because the developing fetus

depends primarily on the maternal supply of essential fatty acids, maternal dietary supplement with LCPUFA-rich oils during the last trimester of pregnancy to increase LCPUFA levels in neonates has been advised. However, the competitive desaturation of the ω-3 and ω-6 series by Δ-6 and Δ-5 desaturases is of major significance because of their controlling role in the desaturating and elongating pathways of the parent essential fatty acids. Thus, excessive dietary intake of LA from vegetable oils, particularly safflower, sunflower, and corn oil, may inhibit Δ-6 desaturase and decrease the formation of DHA from α-LA. Similarly, AA formation is lower when excessive LA is provided, as seen in externally or parentally fed infants receiving corn or safflower oil as the predominant source of fatty.[113] Further, the inhibitory effect of eicosapentaenoic acid on Δ-5 desaturase activity has been considered responsible for the lower plasma AA found when fish oil, high in eicosapentaenoic acid and DHA, is consumed. Also, excessive fish oil intake can inhibit intake of LA from vegetable oils, particularly safflower, sunflower, and corn oil, may inhibit α-6 desaturase activity and decrease AA levels.[114] The consumption of fish oils modifies membrane phospholipid composition, increasing eicosapentaenoic and DHA concentrations at the expense of AA content. Furthermore, adverse effects of low AA concentrations in serum and red blood cell phospholipids on growth during infancy have been observed.[115] AA status in preterm infants also has been correlated with their birth weight.[116] Foods containing lipid peroxides are potentially toxic, and the higher the content of LCPUFAs in the diet, the more likely peroxidation will occur. Thus, excess intake of LCPUFAs may reduce antioxidant capacity, enhancing susceptibility to oxidative damage, a condition that has been shown to be responsible for fetal damage during pregnancy in rats.[117]

Dietary olive oil appears to protect the LCPUFA series better than fish oil.[118] Olive oil also does not affect AA concentrations and is much more resistant to lipid peroxidation. The effect of a diet supplemented with 10% fish oil versus the same amount of olive oil during pregnancy on the fatty acid profile and vitamin E concentration has been studied in the rat. A decrease in AA and α-tocopherol concentrations as well as delayed postnatal development was found in the offspring of rats fed the fish oil–rich diet.[119] This study was extended to determine whether dietary supplementation with either vitamin E or γ-LA as a precursor of AA could ameliorate these changes. AA concentrations and postnatal development indexes, but not α-tocopherol concentrations, were improved when the fish

oil diet was supplemented with γ-LA. In contrast, postnatal development indexes were not improved when the fish oil–rich diet was supplemented with sufficient exogenous vitamin E to normalize άtocopherol levels. Thus, although feeding a fish oil–rich diet during pregnancy and lactation decreased both α-tocopherol and AA concentrations, the latter deficiency rather than the former seemed to be responsible for delayed postnatal development of rat pups. In this same study, another group of pregnant and lactating rats fed the fish oil–rich diet received a supplement with AA instead of ω-LA, and although both treatments restored brain phospholipid content and AA content in the pups, improvement in growth rate and neurodevelopment indexes was more efficient in the γ-LA group. The only difference between the two groups was the absence of LA in brain phospholipids when rats were supplemented with AA, whereas it was present at a normal level in those supplemented with γ-LA.[119] These findings agree with those previously in humans fed diets rich in AA in which the proportion of LA in plasma phospholipids decreased,[120] likely a consequence of replacing LA by AA in tissues.

These observations in humans and experimental animals emphasize the exquisite sensitivity of endogenous LCPUFA metabolism to changes in maternal dietary fatty acid composition during perinatal development and the quite remarkable consequences to fetal and neonatal development. Since benefits and risks of modifying maternal fat intake in pregnancy and lactation are not yet completely established, and the safety of high intakes of LCPUFA during pregnancy is still unclear[121]; further studies are required before recommendations to increase LCPUFA intake in pregnancy can be made.

Fetal Accumulation of Essential Fatty Acids

Intrauterine requirements for LCPUFAs in the human fetus during the last trimester of fetal development through the early weeks of life have been estimated to be 400 and 50 mg/kg/day, respectively. In tissues such as the brain, where lipids constitute about 50% dry weight, almost half of the total lipid content is composed of LCPUFA. Both AA and DHA are readily incorporated into the structural lipids of the developing brain[122] where, besides their role in maintaining membrane fluidity, permeability, and conformation, they play an important functional role. For example, once released from phospholipids by the action of phospholipase A_2, AA is the main precursor for eicosanoids, prostaglandins, and leukotrienes,[74] and it is essential for fetal and neonatal growth, while DHA has a key role

in the development of the retina (both rods and cones, with up to 50% of the fatty acids in the rod outer segment as DHA) and visual function.[123,124] Although the relative rates of desaturation by rat liver and brain differ between those of adult and 10-day-old animals, the degree to which the human fetus is capable of desaturation and elongation is not clear. It is normally believed that the supply of essential fatty acids and LCPUFA is critical and central to the synthesis of structural lipids and hence to normal fetal development.[123,124]

Fetal Lipid Metabolism: Utilization

Physiological changes that develop in the fetus in late gestation and increase nutrient utilization, such as the increase in plasma insulin concentration, act to enhance net maternal-to-fetal fatty acid and lipid transport by increasing fatty acid utilization in the fetus (largely to develop adipose tissue, it appears). Increased utilization of fatty acids by fetal tissues lowers fetal plasma fatty acid concentrations relative to those in the maternal plasma and increases the maternal-to-fetal fatty acid concentration gradients.[99,102] For example, human maternal venous blood concentrations of fatty acids are directly related to the umbilical artery FFA concentrations and the umbilical vein-artery concentration differences of FFAs. Similar observations have been made in the rabbit and the guinea pig, including, in the latter, evidence that experimentally lowering the fetal fatty acid concentration relative to that in the maternal plasma independently increases fatty acid transfer across the placenta (using an in situ perfusion model). Even at the same concentrations, furthermore, naturally occurring or experimentally increased fetal plasma concentrations of albumin directly increase the transfer of fatty acids across the placenta; this observation is based on data from both in vitro perfused human placentas and in situ perfused guinea pig placentas. The effect of albumin seems to be one of simply providing increased esterification capacity in the fetal plasma to bind FFAs transferred directly across the placenta.

When the processes of fatty acid transfer to the fetus by the placenta and fatty acid incorporation into fetal tissues actually begin during gestation, and whether they occur with simultaneous development of placental fatty acid transporters and placental lipid metabolic capacity, remain to be determined, although human fetal fat accretion develops primarily in the third trimester.[3] During late gestation, maternal lipid metabolism changes to a catabolic state, as shown by increased adipose

tissue lipolysis and reduced uptake of circulating triglycerides.[125] The reduced uptake is the result of decreased adipose tissue LPL activity. There is also an overproduction of triglyceride by the liver and enhanced absorption of dietary lipids. Together, these changes in maternal lipid metabolism produce increasing concentrations of nearly all types of circulating plasma lipids as late gestation proceeds, including FFAs, glycerol, and triglyceride-rich VLDL and chylomicron particles. When the pregnant mother is well fed, plasma concentrations of ketoacids (β-hydroxybutyrate and acetoacetate) are not increased, although during fasting, when the concentrations of these substrates do increase, they also may contribute significantly to the supply of nutrient substrates to the uteroplacenta and the fetus.

Fetal Leptin

Leptin mediates a multitude of biological actions in the adult, including regulation of weight by controlling hypothalamic mechanisms involved in food intake and in regulating insulin secretion, insulin action to promote peripheral glucose utilization, and metabolic rate. Emerging evidence supports roles for leptin in the fetus as well, including enhancement of growth.[126] Umbilical cord leptin concentrations correlate with birth weight,[127] being higher in macrosomic infants of diabetic mothers,[128] and lower in infants with IUGR, indicating that the fetal metabolic and hormonal milieu independent of fetal fat content may regulate leptin synthesis and circulating concentrations. In fetal sheep, fetal white adipose tissue leptin mRNA amounts increase with fetal development and gestational age and with basal insulin concentrations.[129] Glucose infusions producing hyperglycemia and hyperinsulinemia and insulin infusions producing hyperinsulinemia alone also increased leptin mRNA, showing that insulin itself can affect fetal leptin production.[130]

Summary of Placental and Fetal Lipid Metabolism

The transport of fatty acids and other lipid substances across the placenta, and the deposition of lipids in adipose tissue, are late-gestation phenomena and highly species specific. The human hemochorial placenta transfers the most lipid and produces the fattest of all land mammals at birth. Essential fatty acid transport, however, occurs in all species and begins early in gestation, allowing membrane lipids, particularly those of neurons, to develop throughout gestation. At preterm birth, however, the human newborn is in a precarious balance with respect to lipid metabolism.

Failure to provide sufficient nonprotein energy will lead to increased rates of lipolysis and fatty acid oxidation. This may or may not result in breakdown of membrane lipids for oxidation, but certainly it produces a metabolic situation in which essential fatty acids will be oxidized along with other fatty acids to produce necessary energy in preference to membrane deposition. This could lead to deleterious reduction in the amount and structure of critical membrane development in the brain, leading potentially to abnormal neurological function and adverse long-term outcome.

Amino Acid Nutrition in Utero: Placental Function and Metabolism

28

Timothy R.H. Regnault, PhD and Frederick C. Battaglia, MD

This chapter will review placental function and metabolism as it relates to the issue of fetal amino acid nutrition. The review will include information available in human pregnancy, although, of necessity, most of the in vivo information has been collected in various animal species, and this, too, will be reviewed. In all mammalian species, the 20 amino acids of the genetic code are required for net protein accretion. The rate of protein accretion has a wide variation among mammals based primarily on gestation length, which ultimately impacts fetal growth rate. The nutritional supply of amino acids for growth is defined as the net umbilical uptake of amino acids, representing the net transfer from the placenta to the fetus, including back flux from the fetus to the placenta of essential and nonessential amino acids. In the ovine fetus, where these data are available, the quantity taken up by the fetus clearly exceeds requirements for growth[1,2] and is associated with a high rate of fetal amino acid oxidation.[3] In this review, we aim to detail aspects of fetal amino acid requirements, placental transport, and metabolism of amino acids as well as highlight factors

influencing these processes, such as fetal growth restriction (FGR). In addition, we will discuss umbilical uptake, interorgan cycling, and fetal and placental amino acid utilization, including, specifically, fetal hepatic and hindlimb amino acid metabolism. In concluding this chapter, we will deal with the neonatal implications of fetal amino acid metabolism.

OVERVIEW OF PLACENTAL DELIVERY OF FETAL AMINO ACID REQUIREMENTS

The primary source of nitrogen for the growing mammalian fetus is the circulating maternal free amino acid pool. In considering the primary role of the placenta in the delivery of amino acids to the fetus, it is important to consider the multiplicity of factors that may affect these overall delivery rates. Figure 28-1 presents in diagrammatic form the potential fate of an amino acid that has been transported across the plasma membrane of the microvillous maternal surface into the trophoblast cytosol, prior to its entry into the fetal circulation through the basal membrane (BM). Pathway 1 represents the direct transplacental flux of an amino acid from the maternal circulation across the plasma membranes on the maternal and fetal surfaces of the trophoblast and into the fetal circulation. Pathway 2 represents the delivery of an amino acid that has entered the intracellular pool via protein turnover within the trophoblast. Pathway 3 represents the backflux from the fetal circulation into the trophoblast of the same amino acid, and Pathway 4 refers to the transformation of the amino acid to a metabolite that can then enter the fetal circulation. The latter example would be the transamination of leucine to ketoisocaproic acid, which can then be delivered to the fetus. The algebraic sum of these fluxes represents the net umbilical uptake, which is the nutritionally important measurement because it represents the net supply of the amino acid delivered to the fetus. The relative importance of each of the pathways in determining the umbilical uptake differs among amino acids. Examples of amino acids that are utilized extensively within the placenta (such as glutamate) or are synthesized at a relatively high rate within the placenta (such as glycine) will be described in the following sections. There is already ample evidence to show that, for different amino acids, one or another of these pathways may predominate.

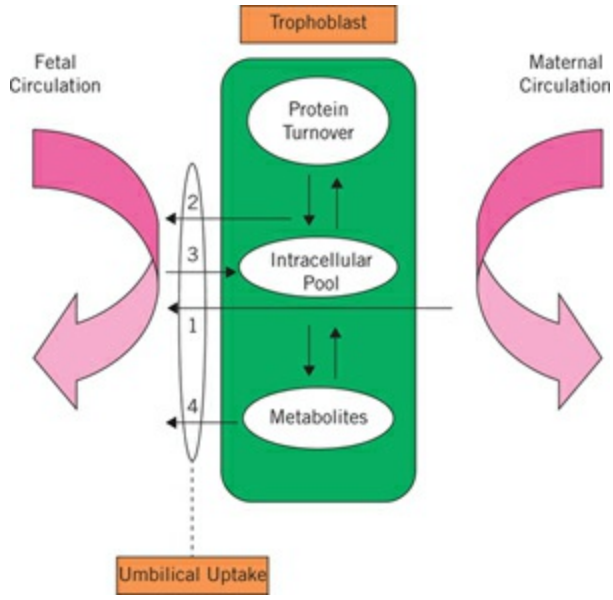

Figure 28-1 A diagrammatic representation of potential pathways for the delivery of an amino acid into the fetal circulation. See text for full description of pathways.

It is apparent that the fetus not only accrues nitrogen in the new tissues formed during growth, but also extensively metabolizes its nitrogen source by synthesizing, oxidizing, and transaminating amino acids.[4] The current estimate of ovine fetal uptake of nitrogen is approximately 0.9 g/kg/d, which is approximately equal to the estimated fetal nitrogen requirement.[5] Therefore, the quantity of amino acids transported is sufficient to meet fetal nitrogen requirements. This estimation includes the fate of amino acids metabolized and excreted as ammonia or urea from the fetoplacental unit.[3,6] Other potential sources of nitrogen, such as intact proteins or peptides, which may be important in embryogenesis do not appear to be required to meet fetal nitrogen needs.

Estimations of fetal protein synthetic rates have been performed in fetal sheep using a variety of methods.[7–9] Leucine was used as a tracer amino acid in chronically catheterized fetal sheep to assess protein synthetic rates at different gestational ages[7,10] and under different physiological conditions.[11,12] These studies demonstrated that the absolute fractional protein synthetic rate (Ks) decreased from mid-gestation to term, and that this decrease was greater than that seen in the fractional protein accretion rate. Figure 28-2 demonstrates the inverse relationship noted

between the fetal Ks and fetal age. Therefore, protein breakdown, defined as the difference between protein accretion and synthesis, decreases in late gestation. The higher protein synthetic rate of the mid-gestation fetus is proportional to the higher metabolic rate at that stage of gestation. Absolute fractional protein synthetic rate declines at a similar rate as fetal O_2 consumption (VO_2), giving a relatively constant ratio of Ks/VO_2.[10] Thus, protein synthesis per millimole of oxygen consumed is quite constant from mid-gestation until term.[10] Fetal metabolic studies, including ones focused upon other metabolic variables such as lactate utilization rate[13,14] and urea production rate,[3,15,16] have advanced our conceptual framework of the key factors that alter metabolic rate per kilogram of body weight during development and, therefore, the developmental changes in the protein synthetic rate.

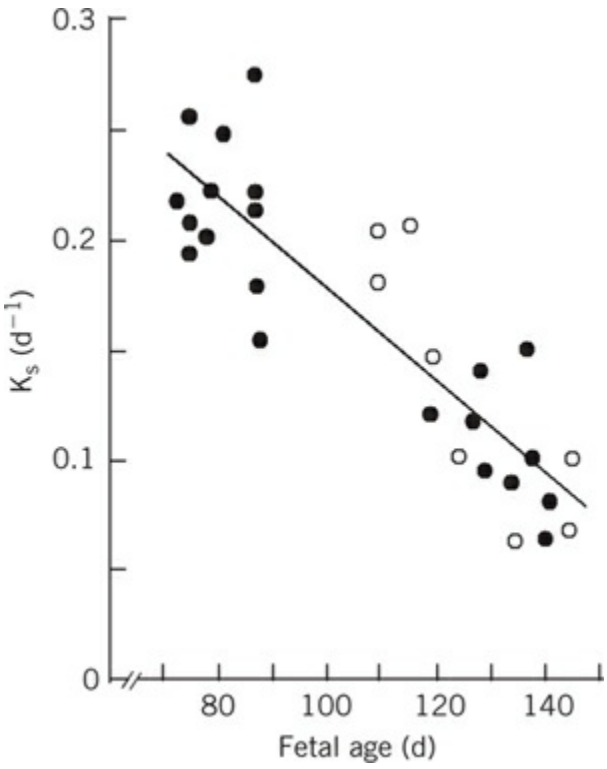

Figure 28-2 In chronically catheterized fetal sheep, the protein synthetic rate (Ks) was noted to decrease with fetal age. Protein synthetic rates were determined using 1^{13} C-leucine (dots) and U^{14}C-lysine (open circles). Regression line (r = –0.87) was drawn according to equation: y = 0.39–0.02Ix. Adapted from Kennaugh et al.[10]

PLACENTAL AMINO ACID TRANSPORT

Both in vivo[5,12,17,18] and in vitro[19–22] studies have brought out the complexity of the placenta as an organ for amino acid transport and metabolism. It is important to emphasize that, unlike an organ such as the liver, the placenta must function primarily as an organ of transport, delivering amino acids from the maternal circulation into the fetal circulation. The complexity of the organ stems not only from the different cell types required to effect such net transport, but also from the capacity of the placenta to metabolize or synthesize various amino acids. The human placenta has two main cell types that are critically important in determining its overall transport characteristics: the trophoblast and the endothelium. In other species, additional cell layers may be present; for example, in the epitheliochorial placenta of sheep and goats, there is an endometrial cell layer as well. However, the syncytium is considered the tissue barrier that is rate limiting to amino acid movement between the maternal and fetal compartments. In any discussion of the human placenta and its tissue layers, it is important to remember that there are enormous changes in the proportion of stem villi to terminal villi at different stages of gestation. Early in gestation, stem villi represent the bulk of the tissue. This means that the interstitial space of the villi and its characteristics for transport and for metabolism cannot be overlooked.

The concentrations of most amino acids, including some of the essentials, are higher in fetal than in maternal plasma, consistent with a process of active transport of amino acids across the placenta. An increased fetal-to-maternal ratio of plasma amino acid concentrations has been documented for humans,[5,23] primates,[24,25] rats,[26,27] guinea pigs,[28,29] sheep,[1,5] and cows.[30,31] The concept of active transport has been corroborated by a variety of experiments. Studies of placental tissue cultured in vitro with nonmetabolizable amino acid analogues, for example, α-aminoisobutyrate (AIB), as well as other amino acids, have shown the intracellular concentration of those substances to be at a level several times greater than the extracellular maternal concentration.[21,32] Placental tissues have also been found to have extremely high levels of the amino acids taurine, glutamate, and aspartate, as well as moderately high levels of alanine, glycine, serine, glutamine, and threonine, when compared to maternal or fetal concentrations.[33] It should be emphasized that measurements of placental tissue amino acid concentrations have not been corrected for extracellular fluid content of the tissue. Therefore, the intracellular tissue concentrations are likely to be considerably higher than

the values in the literature.

The uptake of amino acids occurs through active transport. Mammalian transport systems have been characterized over the years by such general properties as ion dependence, kinetics, substrate specificity, and regulation of activity; and this has allowed the description of multiple transport systems for neutral, anionic, and cationic amino acids, predominantly from human and rat trophoblast studies. Figure 28-3 represents a summary of the major amino acid transport systems described for the maternal microvillous membrane [MVM] and fetal basal membrane (BM) facing membranes of the trophoblast. Each system is distinct but there is extensive overlapping substrate specificity.

System A is a sodium-dependent, unidirectional transporter with a characteristic affinity for *N*-methylated substances, and System A activity has been demonstrated in both MVM and BM.[34] Its activity is increased as an adaptation to cellular depletion of amino acid substrates, similar to that described for System X_{AG}^-[35]; and its mRNA and activity appear to be regulated under a number of factors discussed in more detail in the amino acid protein section.

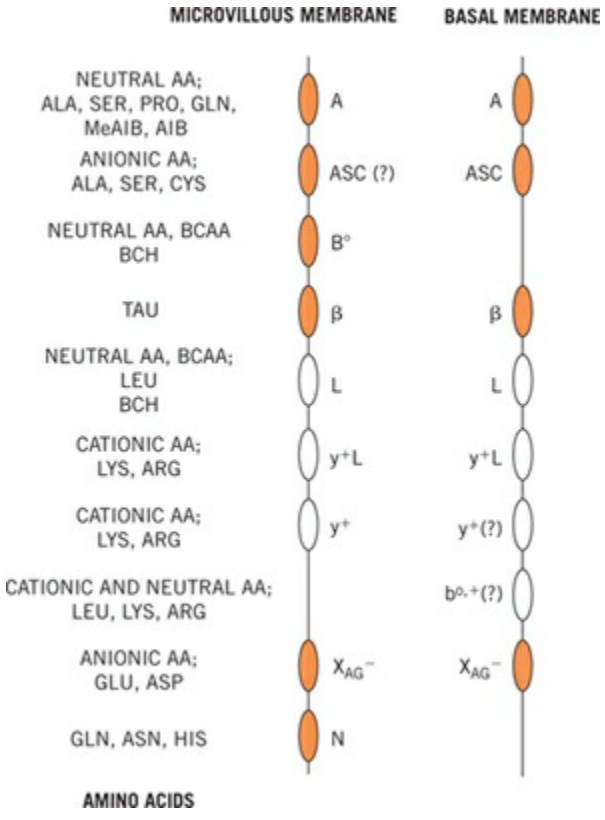

Figure 28-3 Schematic representation of the sodium-dependent (λ) and sodium-independent (γ) amino acid transport systems for both the microvillous (maternal) and basal (fetal) membranes of the trophoblast. Amino acid substrates are listed on the left and references on the right. MeAIB, methylaminoisobutyric acid; AIB, α-aminoisobutyric acid; BCH, 2-aminobicyclo-(2,2,1)-heptane-2-carboxylic acid.

The ASC system has been described for neutral amino acid transport, specifically alanine, serine, and cysteine, as well as for some anionic amino acids.[36] It is a sodium-dependent obligate exchanger localized at the BM, though studies utilizing BeWo cells suggest that System ASC transporters may be present on the MVM as well, but after differentiation and syncytial formation, such activity is lost.[37] A sodium-independent group of transporters (Asc), with similar transport characteristics,[38] has now been reported to exist in placental tissue.[39,40] In addition, the broad-scope, sodium-dependent transporter B^o is responsible for neutral amino acid transport, including branched chain amino acids (BCAAs), and has been localized to the MVM and BM.[41,42] This transporter is highlighted to play an important role in syncytialization, and oxygen tension appears to be a major regulator of its expression.[43] The β-amino acid taurine utilizes the System β transport system. Studies have demonstrated that this β transport system is a sodium-dependent transporter found on both membranes,[44–46] though with a greatly reduced BM activity compared to the MVM.[47] Other studies have now identified this transport system to have a cytoprotective role in syncytiotrophoblasts exposed to hypertonic stress.[48]

System L (or l) transporters are sodium-independent exchange transporters and have been localized to both trophoblast membranes.[49,50] They play a major role in the transport of essential amino acids, having a high affinity for leucine and the other BCAAs.[51–53] The cationic amino acid transport System y^+L is considered a low-capacity, high-affinity system that exchanges cationic amino acids for neutral amino acids and its activity is localized to both the MVM and BM.[54–56] A proposed hypothesis is that this transporter system in the BM is the major supply route of cationic amino acids to the fetus through the uptake of neutral amino acids from fetal circulation, in exchange for cationic amino acids from the placenta.[55,57] The sodium-independent low affinity, high-capacity y^+ transport system is a high-capacity system which transports cationic amino

acids such as arginine, lysine, and ornithine in a sodium-independent manner. It is considered to be the major cationic transport system in placental tissues[5,58,59] and is localized to the MVM[54,55,60] and possibly to the BMs.[61] A role for the related $b^{o,+}$ System in placental tissues has been reported[62,63]; however, further vesicle studies suggest that there is no functional evidence for this system in either term MVM or BM,[55] despite the observation of associated mRNA.[64]

The placenta takes up the anionic amino acids, glutamate and aspartate, from the maternal and fetal circulations, but does not appear to actively transfer these amino acids from mother to fetus. Studies utilizing isolated human and rat placental membrane vesicles and immunohistochemical localization in human placenta have revealed the presence of a high-affinity transport system for aspartate and glutamate via the sodium-dependent X_{AG}^- System within both the microvillous and basal plasma membranes.[34,65,66] This system may mediate the concentrative uptake of anionic amino acids from the maternal and fetal circulations into the placenta. System N transports neutral amino acids, but differs from Systems A and ASC in that it displays a preference for amino acids containing nitrogen-bearing side chains, transporting only glutamine, aspargine, and histidine.[51,67] System N activity is found in the liver and also has been localized in the human placenta,[68] though some studies have failed to report placental mRNA[69] and others have attributed this System N-like transport activity, in the rat placenta, to a combination of System A, possibly System ASC, and $B^{o,+}$ and y^+ L activity.[70]

PLACENTAL AMINO ACID TRANSPORTER PROTEINS

Historically, placental amino acid transport has been described in terms of transport systems based on competitive inhibition studies, though it is now becoming possible to move to a more precise description of the protein chemistry of the transporter system. The ability to clone, sequence, and study the expression of transporters has led to an explosion of data concerning the molecular basis of amino acid transport systems and their potential in vivo function. Thus, the information provided in Table 28-1 and Figure 28-3 should be regarded as an interim report in a rapidly changing field. The identification of individual transporter proteins in the trophoblast will be expanded considerably as sequence data for specific transporters and permit rapid identification of other members of the same

family of transporters; the descriptions in the following section serve to highlight the key points of an expanding field.

TABLE 28-1 Placental Transport Systems and Their Associated Heavy and Light Side Chains

Transporter System	Amino Acid Transporter Type	Protein	Gene
A	Neutral	SNAT-1	SLC38A1
	Sodium dependent	SNAT-2	SLC38A2
		SNAT-4	SLC38A4
ASC	Neutral	ASCT-1	SLC1A4
	Sodium dependent		
Bo	Neutral	ASCT-2	SLC1A5
	Sodium dependent		
β	Neutral	TAUT	SLC6A6
	Sodium dependent		
N	Neutral	SNAT-3	SLC38A3
	Sodium dependent	SNAT-5	SLC38A5
Asc	Neutral	Asc-1/4F2hc[a]	SLC7A10
	Sodium independent	Asc-2/?	SLC7A12
L	Neutral	LAT-1/4F2hc[a]	SLC7A5
	Sodium independent	LAT-2/4F2hc	SLC7A8
		LAT-3	SLC43A1
		LAT-4	SLC43A2
y^+L	Cationic	y^+LAT-1/4F2hc[a]	SLC7A7
	Sodium independent	y^+LAT-2/4F2hc(?)	SLC7A6
y^+	Cationic	CAT-1	SLC7A1
	Sodium independent	CAT-2B	SLC7A2
		CAT-4	SLC7A4
X_{AG}^-	Anionic	EAAT-1	SLC1A3
		EAAT-2	SLC1A2
		EAAT-3	SLC1A1

Refer to text for light chain protein expanded abbreviations.
[a]SLC code for 4F2hc is SLC3A2.

Amino acid transporters exist either as a monomeric protein, while

other transport systems exist as heterodimeric complex.[71,72] Those monomeric transport systems induce amino acid uptake in a similar manner to the amino acid uptake associated with permeases as described in microorganisms,[73,74] though the regulation of placental membrane acquisition of monomeric systems has not yet been studied. Heterodimeric systems involve the grouping together of two proteins to facilitate amino acid transport. In placental tissues, monomeric transport systems are believed to include y^+, ASC, A, and most likely the X_{AG}^- System,[64,75,76] while heterodimeric transport systems include System L, y^+L, and the Asc system.[40,64] Those systems that operate in a heterodimeric manner are generally made up of a common heavy chain, specifically one of the type II membrane glycoproteins, 4F2hc (comparable to the CD98 surface antigen, CD98hc),[76,77] the Neutral and Basic Amino Acid Transport (NBAT), equivalent to rBAT or D2[78–80] protein or as yet undefined proteins,[39] which associate with one of a variety of light chain transport proteins, providing a range of amino acid transport systems.[81,82] There is also evidence that these heavy chains may interact with themselves and each other to form homodimers and/or heterodimers before interacting with a specific light chain to induce activity.[55] A summary of the traditional transport systems and their heavy and light chain associations that have been reported in placental tissues and membranes is presented in Table 28-1.

The 4F2hc mRNA is ubiquitously expressed.[72] While 4F2hc is expressed in placental tissues throughout pregnancy, NBAT expression appears only in first and early second trimester placenta and has not been reported in term tissues.[55,83]In human and rat pregnancy, whole-tissue studies have demonstrated 4F2hc predominantly in the MVM, with the content increasing as gestation advances.[55,77,83] However, 4F2hc has not been detected in the human BM,[55,77] despite reports of 4F2hc mRNA in rat BM preparations[83] and evidence that 4F2hc plays a role in BM amino acid transport in other tissues, including the intestine and kidney.[84]

The glycosylated 4F2hc protein is composed of a single transmembrane region with a large C-terminal extracellular domain.[85] Since mammalian substrate transporters appear to have multiple transmembrane helices, it is unlikely that the 4F2hc protein is capable of inducing amino acid transport alone.[86] It is postulated that 4F2hc is in fact the modulator of heterodimeric transport systems and acts as a “guidance molecule,” translocating the nonglycosylated light chains to the plasma

membrane, after which disulfide linkage between 4F2hc and the light chain occurs.[72,87] The subcellular location of the light chain proteins and their interaction with 4F2hc protein is not well defined. Presently, the model of interaction involves an intracellular pool of light chains that are available for incorporation with the membrane-bound heavy chain.[75,85] The movement is independent of the formation of the disulfide bonds, which suggests a noncovalent steric association.[88] Following membrane localization and, if required, light chain and heavy chain interaction, functional transport may then occur.[72,89,90] The expression of the heavy chain, and not that of the light chains, is best correlated with placental amino acid transport system activity.[75,85]

Neutral Amino Acid Transporter Light Chain Proteins

Currently, three subtypes of the amino acid System A have been cloned, amino acid transporter SNAT1 (SLC38A1), SNAT2 (SLC38A2), and SNAT4 (SLC38A4), and all systems appear to operate in a monomeric manner.[72] The SNAT1 (ATA-1 or GlnT)[91] system has a limited tissue expression, being expressed predominantly in the human placenta and heart, and is responsible for the transport of small short-chain neutral amino acids, such as alanine, serine, methionine, asparagine, and glutamine.[91] The functional characteristics of SNAT2 are similar to those of SNAT1, though found in a wider range of tissues, including the placenta.[91,92] SNAT4 initially appeared to have a unique tissue distribution predominantly in hepatic and skeletal muscle tissues;[93] however, reports also place it in the placenta, in both human MVM and BMs, being expressed from early pregnancy onwards, similar to SNAT1 and SNAT2.[94]

Studies are now identifying the many factors that relate System A expression and activity. These include a number of maternal and fetal influences such as maternal growth hormone (GH),[95] activation of insulin/insulin-like growth factor -I (IGF-I) and mammalian target of rapamycin (mTOR) signaling pathways,[96,97] hypoxia,[98,99] Interleukin 6(IL-6),[100] and leptin concentrations.[101] Other impacts such as amino acid restriction,[102,103] maternal diet,[104] dietary fat and fiber levels,[105] and specifically fatty acids via placental toll-like receptor 4 are also reported to impact System A activity.[106] Maternal age also impacts System A expression, where teenage placentae have been characterized as having reduced System A mRNA, though there appears to be increased activity in

growing teens.[107] Of final note, it appears that synthetic glucocorticoid administration may regulate System A activity, though in a differential manner. In mid-gestation it appears to be associated with decreased System A activity,[108] while near term it is associated with System A activity activation and promotes syncytiotrophoblast differentiation and maturation.[109]

The ASCT-1 (SLC1A4),[110] a component of the ASC transport system, has been localized to human placenta tissue, though its expression appears to be very low.[111] Another component of the ASC system, ASCT-2 has also been cloned,[112] though this is thought to code protein related to the related transport family System Bo. The Bo is a sodium-dependent neutral amino acid transport system for which the related gene ASCT2 (SLC1A5) is proposed to represent the Bo system in the human placental choriocarcinoma cell line, JAR, and isolated human placental Poly(A)$^+$ mRNA.[42] The B title represents this system's broad substrate preference, and the capital status indicates its sodium dependence. The superscript o defines it as accepting zwitterionic or neutral amino acids, which distinguishes it from the Bo,$^+$ system, which also accepts cationic amino acids.[42,113] In early pregnancy, prior to implantation, leucine uptake through System B$^{o,+}$ in blastocysts triggers mTOR signaling believed to result in trophoblast motility and the onset of the penetration stage of blastocyst implantation,[114] and in culture systems altered oxygen tensions appear to play a regulatory role.[43] It has been postulated that suboptimal System Bo,$^+$ regulation of these early pregnancy developmental processes may influence placentation and subsequent embryo nutrition, birth weight and risk of developing metabolic syndrome and obesity.[114] These systems (Boand Bo,$^+$) are differentiated from the bo,$^+$ system that also transports neutral and cationic amino acids, but in a sodium-independent manner.[115] This latter system has been reported in BM preparations,[61] though this localization has been questioned with its activity attributed instead to the y$^+$ L system, as no functional evidence for System bo,$^+$ has been observed in term MVM or BM.[55] The β transporter for taurine has exhibited activity in placenta apical and basal placental preparations,[44,116,117] and this activity is associated with a mRNA encoding TAUT (SLC6A6), in placental cell lines and human placental Poly(A)$^+$ mRNA.[117,118]

The sodium-independent transport of small neutral amino acids is carried out by the Asc system, comprising the proteins, Asc-1 (SLC7A10) and Asc-2 (SLC7A12), both of which have been identified in placental

mRNA.[39,40] Asc-1 forms a heterodimeric complex with 4F2hc (SLC3A2),[40] whereas Asc-2 appears to interact with a presently unknown heavy chain.[39]

Other light chain proteins also associate with 4F2hc to form the functional L transport system,[75,89] catalyzing the uptake of neutral amino acids in a sodium-independent manner. System L-amino acid transporter-1 LAT-1 (SLC7A5), LAT-2 (SLC7A8), LAT-3 (SLC43A1), and, LAT-4 (SLC43A2) have all been reported in placental tissues.[75,77,90,119] The 4F2hc/LAT-1 transport activity displays a narrow specificity towards neutral amino acids, uninfluenced by pH, while 4F2hc/LAT-2 activity has a broad specificity and is stimulated by decreasing pH.[120] Immunological and functional studies suggest that at term, the light chain, LAT-1 is located predominantly in the MVM and the syncytiotrophoblast layer of the villi.[38,77,121] Furthermore, the L transport system phenotype associated with that of the placental MVM is found to occur when the LAT-1 and not the LAT-2 catalytic subunit is co-expressed with the 4F2hc.[121] In a similar manner, human LAT-2 mRNA has been identified in the choriocarcinoma BeWo cell line and placental villous tissues[121,122] and its activity has been localized to the BM[38,121] and not the MVM as is the case for LAT-1.[90,121,123] These studies suggest that the localization of system activity may be further defined through specific light chain location. LAT-1 and LAT-2 function as classic obligatory exchangers, moving substrates in exchange for other amino acids,[124,125] and appear unaffected by hypoxia.[98] Two additional System L light chains, LAT-3 and LAT-4 have recently been reported in placental tissues.[119,126] They appear localized to the BM, are present in the human placental BM, and may play an important role in the net efflux of amino acids to the fetus.[22] While transporting a restricted group of System L substrates (leucine, isoleucine, and phenylalanine) they also appear to differ from the traditional System L transport in that they do not appear to require the co-expression of 4F2hc, and they function as facilitative diffusion transporters.[125,126]

Cationic Transport System Light Chain Proteins

Transport of cationic amino acids occurs predominantly through the y^+L and y^+ systems. Placental y^+L system activity is determined by which light chain, System y^+L-amino acid transporter-1 (y^+LAT-1, SLC7A7) or System y^+L-amino acid transporter-2 (y^+LAT-2, SLC7A6), forms a heterodimer with the membrane-bound 4F2hc. Human placental

preparations contain y^+LAT-1 mRNA,[55,56,127] and when this mRNA is co-expressed with 4F2hc in *Xenopus laevis oocytes*, amino acid uptake characteristics similar to that of System y^+L are displayed.[82] Presently, it is unclear if System y^+LAT light chain proteins display a tissue distribution pattern similar to that displayed by the LAT proteins. However, this system appears to provide an essential role in supplying cationic amino acids to the fetal circulation by exchanging cationic amino acids from within the trophoblast for neutral amino acids such as glutamine and leucine from fetal circulation.[57,127] This mode of operation provides a route of efflux, overcoming the outward positive potential difference across the trophoblast basal plasma membrane.[52]

System y^+ activity is dependent only on the expression of monomeric proteins (or the CAT gene products).[63,128] Currently there are three known mRNAs, which encode for proteins related to this cationic amino acid transport system in placental tissues, namely the cationic amino acid transporters CAT-1 (SLC7A1), CAT-2 (SLC7A2), and CAT-4 (SLC7A4).[55,58] This system's activity has been reported in membrane preparations of the rat and human placenta,[50,62] with a higher uptake in the MVMs compared with the BM.[50,129] However, in the human, contrasting kinetic and substrate inhibition studies and RT-PCR studies localizing CAT-1 and 4 mRNA in human placental tissue suggest that y^+ activity is limited to the MVM and not the BM.[55]

Anionic Transport System Light Chain Proteins

Five cDNA-encoding proteins capable of mediating high-affinity sodium-coupled transport have been reported, and three of these have been cloned from placenta tissue.[65,130] These placental proteins, excitatory amino acid transport (EAAT)-1 (GLAST1), EAAT-2 (GLT1), and EAAT-3 (EAAC1), are known to mediate placental sodium-dependent D-aspartate-inhibitable anionic amino acid transport or System X_{AG}^- activity.[130] All three forms have been detected in human placental tissue[66,131] and in rat placenta tissues.[65,132] The regulation of these proteins also appears to be under the control of GH and IGF family members,[132] and upregulation of the system has been demonstrated through cell density and nutrient deprivation studies in muscle and placental cell lines.[35,65] These latter studies further demonstrated that EAAT-1 and EAAT-3 play a key role in the basal anionic amino acid transfer, while EAAT-2 may be involved in conditions of amino acid depletion.[65]

PLACENTAL AMINO ACID TRANSPORT DURING PREGNANCY

As pregnancy advances, the increasing nutrient demands of the developing conceptus must be met through an appropriate increase in placental nutrient transport. This enhanced performance is facilitated through alterations in placental perfusion and changes in membrane exchange surface area. Recent studies in human pregnancies have shown that total umbilical blood flow increases during gestation in a pattern similar to fetal growth rate. The relationship between blood flow and body size is quite good, although not perfect. As shown in Figure 28-4, when blood flow is expressed per kilogram fetal weight, it falls slightly throughout gestation. This pattern of decline is similar to the changes in fetal heart rate in human pregnancies, which also decreases as gestation advances. Heart rate is closely linked to metabolic rate. Thus, the changes in blood flow and in fetal metabolic rate appear to be reasonably well linked in human pregnancies. The decrease in umbilical blood flow per kilogram fetal weight in human pregnancies does not present a problem in terms of supplying amino acids to the fetus as it grows, as changes in blood flow are compensated for by an increase in placental surface area, and presumably an increase in the number of membrane-bound transporters available for delivery of amino acids. Between the 16th week of pregnancy and term, human fetal weight increases approximately 20-fold, whereas the peripheral villous surface area increases only ninefold.[133,134] It should be emphasized, however, that there are only a few careful ontogenetic studies of how total surface area, including microvillous surface, changes over gestation.[135–137] Furthermore, the most important aspect of human fetal development is the acquisition of huge fat stores, most of which occurs in the last few months of pregnancy.[138] During this time, there is almost no increase in nitrogen content while body fat increases exponentially. Hence, it is carbon that must be acquired, not nitrogen, during these last few months of pregnancy.

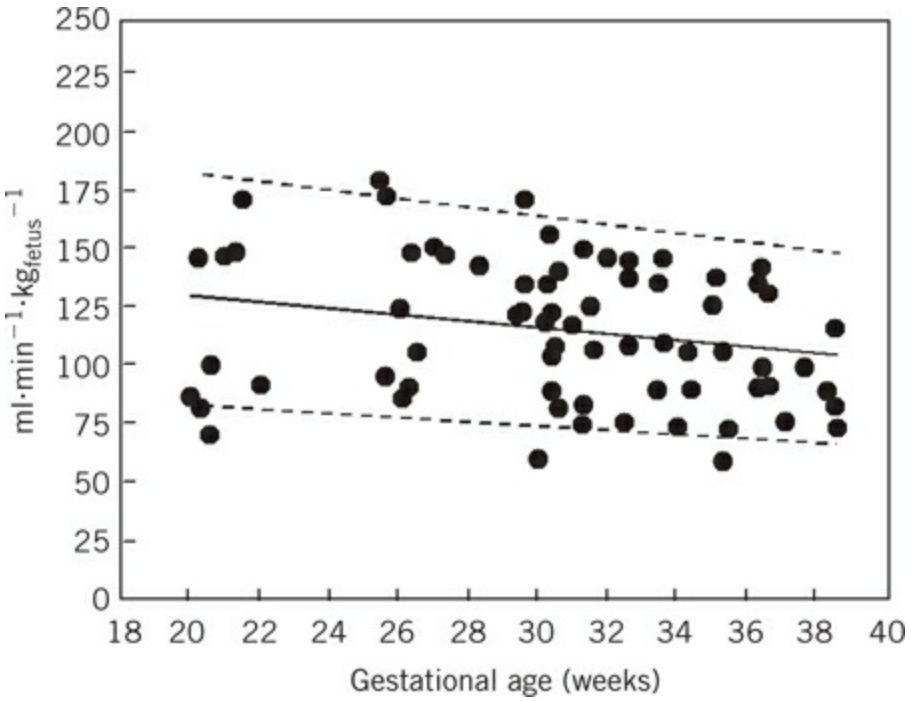

Figure 28-4 Umbilical vein blood flow per kilogram of fetal weight plotted against gestational age for human pregnancies. Slight linear decrease observed was not significant ($y = –1.3636x + 155.9964$). Both 5th and 95th percentiles are shown (dashed lines). Adapted from Barbera et al.[215]

The increases in total surface area of the placenta alone cannot account for the exponential fetal growth occurring over the latter half of gestation. These data suggest the total transport capacity of the trophoblast is likely to be determined by total villous surface area, placental permeability, the concentration of specific amino acid carrier proteins on the cell membrane surfaces, as well as the affinity/activity characteristics of transporter proteins and the circulating amino acid concentrations at both the maternal and fetal surfaces. Indeed, as gestation advances, the efficiency of the placenta as reported as fetal weight per 1 g of placenta increases.

Accompanying the maturational changes in trophoblast surface area, amino acid transport systems are reported to have differing expression and transport parameters through gestation.[55,77,139,140] For example, in term placentae, L-arginine transport in MVM preparation is through both y^+ and y^+L systems, while in the BM transport this may be restricted to the y^+L system.[55] Furthermore, the functional properties of transport systems may

also change as gestation advances. For example, first trimester MVM has increased transport activity compared to term placental vesicles,[140] and 4F2hc protein levels differ between early/mid-pregnancy and term placentae.[55,77] Early in gestation the Km of the MVM high-affinity System y^+L is significantly less than in term preparations.[55] Such studies highlight the complex interactions that occur between developing MVM and BM, within the trophoblast and between the two circulations, to facilitate an increase in nutrient delivery to the growing fetus as gestation advances.

FETOPLACENTAL AMINO ACID METABOLISM

The amino acid requirements of the placenta for energy and for protein accretion during its growth are not well known. The placenta contains enzymes related to carbohydrate and amino acid metabolism that give it the capacity to oxidize a number of amino acids as well as perform glycolysis, glycogenolysis, and glycogen, protein, and fatty acid synthesis.[141,142] Four amino acids (alanine, glutamine, threonine, and serine) that are found in high concentrations in placental tissues and are known gluconeogenic precursors, are transported by the three transport Systems, A, L, and ASC,[38,52,64] which could be a protective mechanism to ensure adequate fetal supply of these important amino acids. So far, amino acid oxidation by human placental mitochondria has been demonstrated for alanine, aspartate, glutamate, and glycine.[143,144] Additionally, given the data on the large uptake of glutamate by the ovine placenta from the fetal circulation, it is possible that glutamate is a predominant amino acid functioning as a metabolic fuel for the placenta[145] where metabolic requirements are very large. In vivo estimates of its oxygen consumption are approximately equal to those for the brain, and oxidation of amino acids is a major metabolic function of the placenta.[146] In vivo, there is a significant production and excretion of ammonia into both uterine and umbilical circulations by the ovine and human placenta.[6,15,16] The absolute rate of uteroplacental ammonia production, approximately 25 μmol/min in the ovine pregnancy at mid-gestation (73–97 days, term 147 ± 3 days), is approximately equal to that of the term placenta. Since in vitro data indicate that there is minimal urea cycle activity within the placenta,[146] this suggests that ammonia, and not urea is the end product of amino acid deamination within the placenta. Some of the ammonia produced by the placenta is consumed by the fetal liver and, in fetal sheep near term, the uptake by the fetal liver is approximately 1.5–1.8 times that taken up by

the umbilical circulation from the placenta.[6,15,146] This indicates that fetal tissues, as well as the placenta, produce ammonia, and uptake of ammonia by the fetal liver undoubtedly contributes to its high rate of fetal urea production.

In part, the placental ammonia production is derived from the transamination of BCAAs.[147] The activity of the branched chain aminotransferases is high in the placenta, and since the activity of α-keto decarboxylases is low, it is clear that the α-ketoacids derived from the BCAA are not oxidized further. These α-ketoacids represent part of a group of compounds that are produced in the placenta and are delivered into both uterine and umbilical circulations. These compounds include ammonia, lactate, and one of the polyols, sorbitol (Figure 28-5). The placental production of glutamate as a consequence of transamination of α-ketoglutarate from BCAA,[145,148,149] together with the placental uptake of fetal plasma glutamate at 4.8 μmol/min/kg fetus,[145] represent the two major influxes of glutamate into the ovine placenta. Although the ovine placenta contains the enzyme glutamine synthetase, only a small fraction of glutamate that is taken up by the placenta from fetal circulation is returned to the fetus as glutamine.[145,150] It is the oxidation of glutamate that appears to be the predominant pathway of placental glutamate disposal.

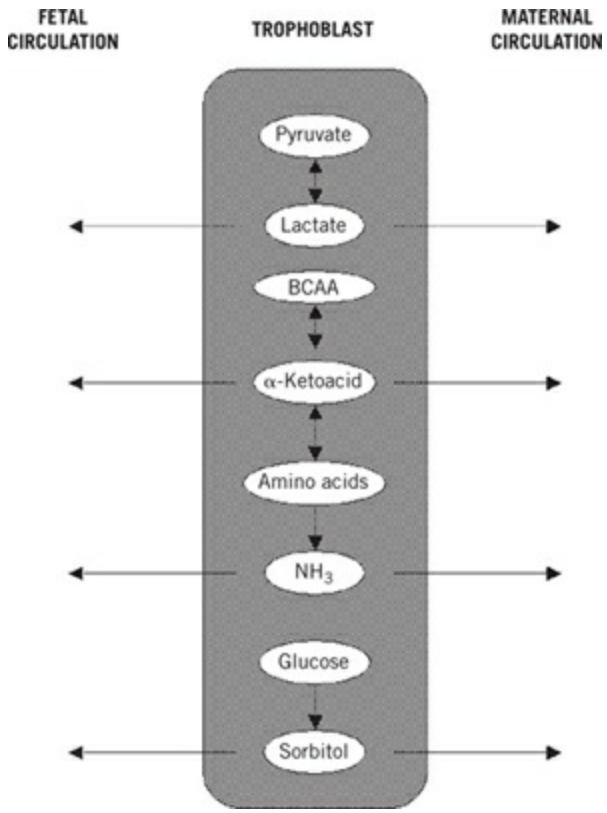

Figure 28-5 A schematic representation of some of the metabolites produced in the placenta that are then delivered into both the maternal and fetal circulations.

It is likely that placental ammonia production is not confined to the epitheliochorial placenta of the sheep. It has been described for the perfused human placenta, and a net efflux of ammonia from the pregnant uterus into the maternal circulation has also been found in rabbits, guinea pigs, and sheep.[148,150–152] It is intriguing to speculate on the possible biologic significance of mammalian fetuses growing and developing in an environment of an elevated ammonia concentration. Finally, ammonia can affect hepatic metabolism and may play a role in glial development and in the development of other tissues rich in glutamine synthetase.

UMBILICAL UPTAKE OF AMINO ACIDS

The umbilical uptake of amino acids (Figure 28-1), is the key step marking the delivery of amino acids into fetal circulation following placental uptake and metabolism. A number of studies involving examination of the

umbilical uptake of amino acids in chronic, unstressed sheep models have revealed that most amino acids (particularly the neutral amino acids) are delivered into the fetal circulation in amounts that exceed their net rates of accretion.[2,5,16,149] The most complete data on the uterine and umbilical uptakes of amino acids are presented in Figure 28-6. 149 A key question, however, is: Upstream of this ultimate delivery to the fetus, how are maternal concentrations of amino acids related to the umbilical uptake? This question is important because it would help define the extent to which changes in maternal amino acid concentrations could impact the fetal delivery of amino acids. The question has been studied in both ovine and human pregnancies by infusions of amino acids into the maternal circulation with measurements of their umbilical uptake. The relationship between maternal concentration and umbilical uptake is a complex one. In ovine studies, the flux from the maternal circulation to the fetal circulation is most rapid for five amino acids and for those five (methionine, phenylalanine, leucine, isoleucine, and valine), differences in their fluxes are directly attributable to differences in their normal maternal plasma concentrations,[17] as shown in Figure 28-7. In sheep and human pregnancies, it is possible to increase the fetal delivery of most amino acids by increasing the maternal concentration in normal pregnancies.[16,153] This appears also to be the case for pregnancies complicated by FGR.[23,154] However, for some amino acids, it has not been possible to increase placental transport when an infusion of many amino acids is given to the mother, presumably due to competitive inhibition by other amino acids in the infusate.[16] Indeed, the description given earlier of the multiple transporter proteins and their amino acid specificity is complex (probably due to difficulties in standardizing techniques for isolating tissue membrane fragments); however, the general principle that emerges is that all transporters from the in vitro and in vivo studies, virtually without exception, are utilized by several amino acids. This simple observation explains the difficulties encountered in trying to increase the delivery of amino acids to the fetus by infusions of amino acids into the maternal circulation. Competitive inhibition has been well demonstrated in vivo leading to a decrease in transport of some amino acids to the fetus despite an increased concentration in the maternal circulation.[16] It also explains the futility of attempting to establish a constant amino acid concentration in the fetus (an amino acid clamp) by a fetal infusion of amino acids. Competitive inhibition will lead to inhibition of the entry of amino acids into the fetal tissues when other amino acids are increased.

Measurements of unidirectional flux are currently available only for the ovine species. A number of studies involving examination of the umbilical uptake of amino acids in chronic, unstressed sheep models have revealed that most amino acids (particularly the neutral amino acids) are delivered into the fetal circulation in amounts that exceed their net rates of accretion.[5,16,149,155,156] The most complete data on the uterine and umbilical uptakes of amino acids are presented in Figure 28-6.

Several studies of the umbilical uptake of amino acids under normal conditions have shown that there is no measurable uptake of aspartate and, in fact, a significant net uptake from the fetal circulation into the placenta of serine and glutamate. Thus, for these three amino acids, it is clear that fetal requirements must be met by production within fetal tissues. Stegink et al.[25,157] infused labeled tracer isotopes of glutamate and aspartate into both fetal and maternal circulations of rhesus monkeys and found essentially no transfer of the compounds across the placenta. Schneider et al., [158] utilizing an in vitro–perfused human placenta preparation, found significant uptake of glutamate from the fluid perfusing the fetal side of the placenta rather than a net transfer of glutamate from the maternal to the fetal side.

It is clear that the umbilical uptake of amino acids cannot be considered solely a reflection of the amino acid supply derived from the maternal plasma pool via transplacental transport, but also may include a contribution derived from production within the placenta or release from placental breakdown.[159] It is important to understand which amino acids are provided to the fetus primarily through placental production versus placental transport, because differing forms of placental pathology may adversely affect the mode of delivery of those amino acids to the fetus.

FETAL AND PLACENTAL OXIDATION

The use of multiple-tracer methodology in animal models has allowed further elucidation of amino acid metabolism within the placenta and the fetus. Fetal and placental metabolism of the essential amino acids, leucine and threonine, have been studied in some detail.[18,160–162] For leucine, Loy et al.[160] were the first to demonstrate that even for an essential amino acid there may be extensive catabolism both within the fetus and within the placenta. They found that 20%–25% of the (1-^{14}C) leucine infused into the fetus could be accounted for as $^{14}CO_2$ produced by the fetus. Unlike glutamate, there was no measurable oxidation of leucine within the

uteroplacental tissues. This indicated an extensive utilization of leucine as a fetal but not placental fuel. From the sheep studies, the extensive fetal catabolism of leucine can be better appreciated by a comparison of its supply to the fetus via the placenta and its rate of oxidation and of accretion in tissue protein. The total umbilical uptake of leucine is approximately 4.9 μmol/min/kg, and net accretion of leucine in tissue proteins accounts for only 2.0 μmol/min/kg in late gestation. On the other hand, the rate of leucine oxidation is 2.8 μmol/min/kg or 57% of its uptake.

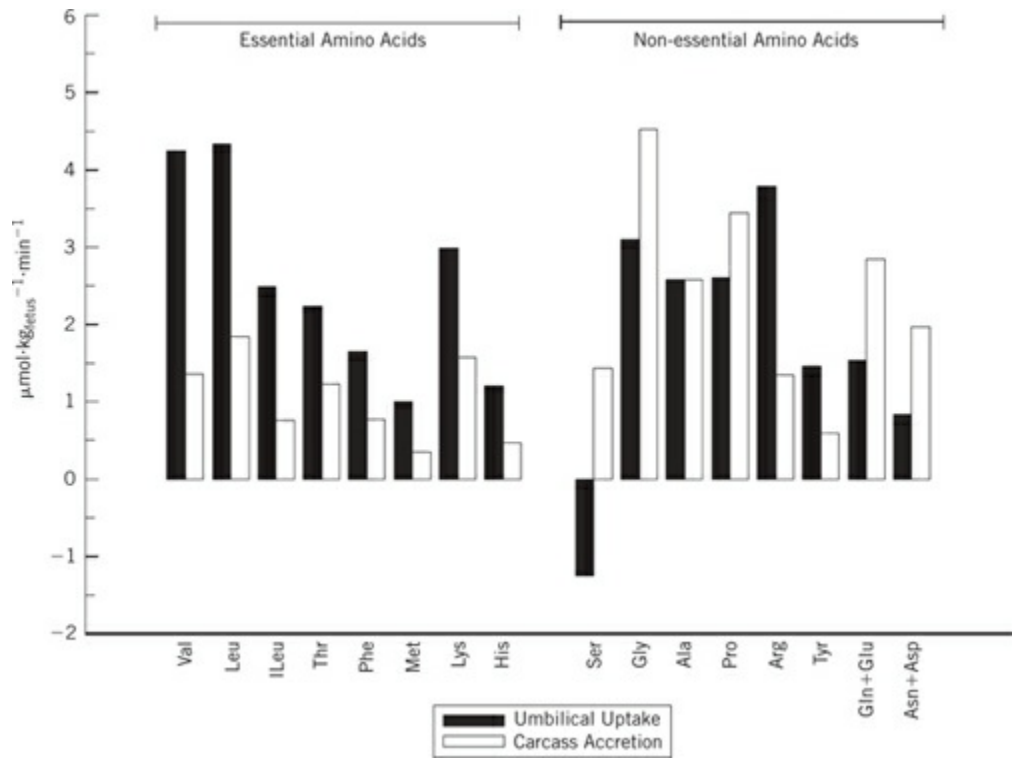

Figure 28-6 Comparison between mean umbilical uptakes and estimated normal fetal accretions of amino acids. For pairs of amino acids (glutamine + glutamate and asparagine + aspartate) individual accretion rates are not known. Adapted from Chung et al.[149]

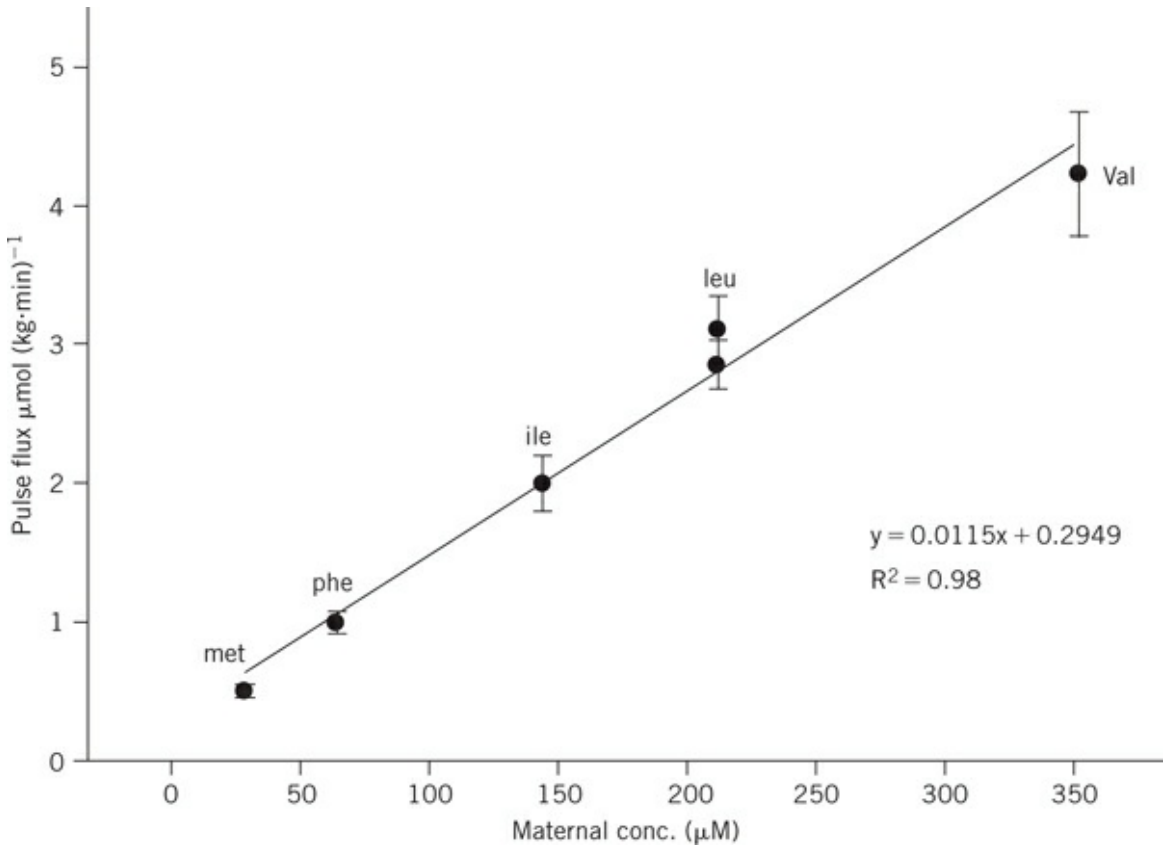

Figure 28-7 Pulse flux calculated over the first 10 minutes after the bolus versus maternal plasma arterial concentration for the five essential amino acids that have high and similar pulse flux clearances. The two leucine data represent two separate studies. Adapted from Paolini et al.[17]

The oxidation rates of amino acids in the fetus and/or placenta of human and predominantly sheep preparations have been measured for leucine, lysine, threonine, alanine, glycine, serine, and glutamate[17,145,160–164]; and it is apparent that fetal oxidation of amino acids is not confined to the nonessential amino acids. In fact, it is an important safety feature for fetal nutrition that amino acids are provided in amounts which exceed their rates of accretion.[3,5] This mandates a fairly high oxidation rate for most amino acids including the essential amino acids. It is not surprising, therefore, that there is a relatively high rate of urea production by the fetus. In the sheep this has been shown by direct measurements of $^{14}CO_2$ production from labeled amino acids and from the high fetal urea production rate in the fetal lamb,[3] and estimated for the

human fetus.[165,166]

FETAL HEPATIC CIRCULATION AND AMINO ACID METABOLISM

The umbilical vein carries the most oxygenated and nutrient-rich blood of the fetus and a large fraction of this blood perfuses the fetal liver. Thus, the fetal liver, in contrast to the postnatal liver, is a site of preferred oxygenation. It is a vitally important defense for the fetus during periods of chronic or acute hypoxia, because it continues to take up lactate from the fetal circulation and releases pyruvate. Other fetal tissues can then metabolize pyruvate. For human pregnancies, the percent of umbilical blood flow shunted away from the fetal liver through the ductus venosus has now been measured.[167] The shunt gradually decreases from 40% to 15% over a gestational age range from 20 weeks to term. However, in some FGR pregnancies, this shunt is significantly increased.[167,168] Since other studies have shown a reduction in umbilical blood flow per kilogram fetal weight in FGR pregnancies,[169] this in itself reduces perfusion of the fetal liver. However, if the reduction in umbilical flow is coupled with an increased ductus venosus shunt, the decrease in hepatic perfusion can be profound. These changes in the fetal circulation must be kept in mind in terms of their potential importance upon fetal hepatic metabolism.

Fetal hepatic uptake of amino acids has been studied in late-gestation fetal lambs, and fetal hepatic uptake and the umbilical uptake of amino acids have been compared.[170] A large hepatic uptake of the entire essential and most of the nonessential amino acids by both lobes of the fetal liver has been reported.[5] During normal fetal development, there is no appreciable rate of fetal gluconeogenesis. This is understandable since fetal hepatic glucose production would be self-defeating for the fetus. It would increase plasma glucose concentration, which would reduce the transplacental glucose gradient leading to a reduced umbilical glucose uptake from the mother. The absence of fetal gluconeogenesis is not accompanied by a reduced amino acid uptake in the fetal circulation from the placenta,[149,171] as shown in Figure 28-8. There is a large uptake of amino acids, including all of the gluconeogenic amino acids, as well as a large fetal uptake of lactate. In fetal life, the carbon is released primarily as glutamate and pyruvate with a smaller contribution occurring with the hepatic release of serine, ornithine, and aspartate. This is in contrast to what occurs in postnatal life, where the carbon from these amino acids is

released from the liver solely as glucose. The hepatic uptake of lactate and release of pyruvate are of special interest because of the importance of these compounds during fetal hypoxia. The uptake of lactate and release of pyruvate continues under conditions of fetal hypoxia providing pyruvate, which can be metabolized by nonhepatic tissues even under hypoxic conditions. The hepatic metabolism of lactate and production of pyruvate help explain the paradox of severe fetal hypoxia associated with a relatively normal pH.[172]

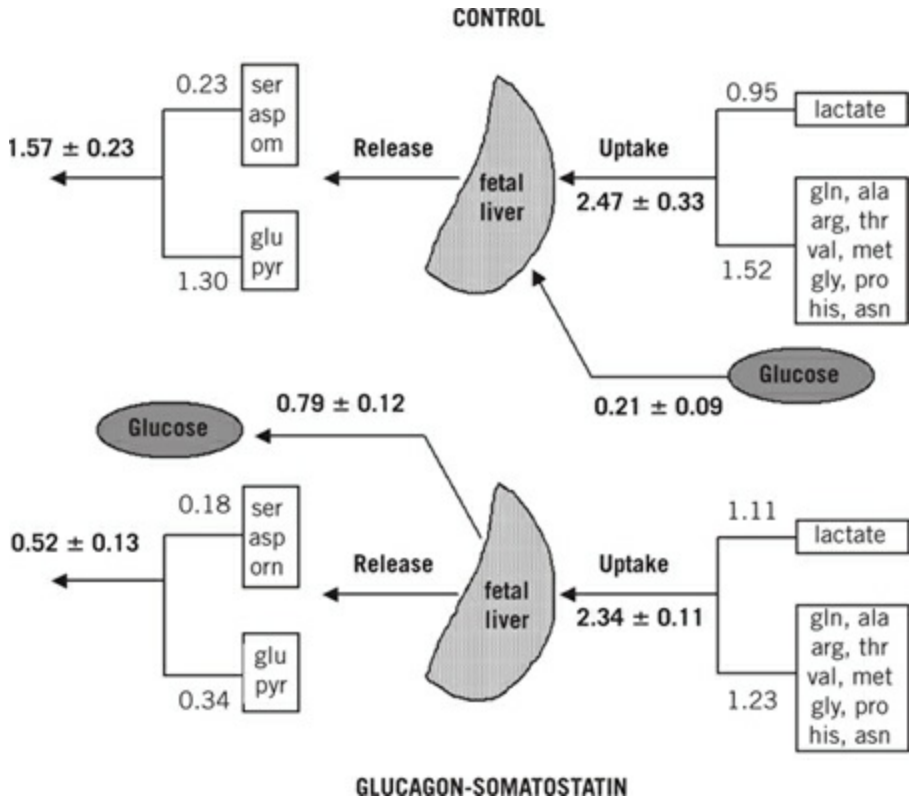

Figure 28-8 Fetal hepatic uptake and output of glucose carbon and glucogenic substrate carbon under normal physiologic conditions (Control) and during a fetal glucagon somatostatin infusion. Each number represents a substrate carbon to oxygen uptake ratio. Adapted from Teng et al.[171]

The interorgan shuttling of the two amino acid pairs, glutamate and glutamine and serine and glycine, play an important role in this overall carbon balance for the fetus. The release of glutamate, serine, and pyruvate effectively replaces the glucose carbon release characteristic of the liver in postnatal life. This is clearly brought out in Figure 28-8, which shows what

happens when gluconeogenesis is triggered in the fetal liver by the infusion of glucagon.[171] With the advent of net glucose released from the liver, the efflux of glutamate, serine, and pyruvate is markedly reduced, and the overall carbon balance is maintained. The exchange of glutamate and glutamine between the fetal liver and placenta does not represent a cycling of carbon between the two organs, as glutamate is largely oxidized in the placenta and in the fetus.[145] The exchange of glutamate and glutamine changes quite markedly during parturition and during glucocorticoid or glucagon administration to the fetus.[171,173] Under these conditions, there is a decrease of fetal hepatic glutamate release that results in a decrease of placental glutamate uptake. What role these metabolic changes in the fetal liver play in parturition is not yet established.

Glycine and serine are a metabolically related pair of amino acids that demonstrate a similar pattern of release and uptake across the ovine fetal liver and placenta to that of glutamate and glutamine,[5,174–176] and there are now studies reporting their metabolism in human pregnancy.[177] The fetal glycine oxidation rate is high, and glycine is almost totally oxidized within the fetal liver. Fetal hepatic glycine oxidation and serine production from glycine are linked in the fetal liver by the enzyme systems glycine oxidase and serine hydroxymethyltransferase (SHMT).[178,179] The combined action of these enzymes is the production of one mole of CO_2 and one mole of serine for every two moles of glycine consumed.[174,180] This is also true in adult tissues,[181] though the adult liver is not normally a site of net serine release.[182]

Infusion of tracer serine into the fetus has demonstrated a rapid bidirectional transport of serine between the fetal blood and placenta, as well as placental conversion of fetal plasma serine to glycine. In contrast to glycine oxidation, the bulk of fetal plasma serine oxidation occurs in extrahepatic tissues.[164,180] Moores et al. infused labeled serine into the maternal circulation of pregnant sheep and found that despite high maternal enrichments of serine, there was no fetal plasma enrichment evident. However, the infusion of maternal tracer serine did lead to the appearance of labeled glycine in the fetal circulation. Thus, placental glycine production utilizes serine derived from both the maternal and fetal circulations.[164] This brings out the complexity of pathways by which an amino acid such as glycine is delivered to the fetus from the placenta. The pathway for glycine production from serine is thought to be via serine SHMT, since ovine placental tissue is known to have moderately high activity for the mitochondrial isoform of this enzyme.[164,179] A byproduct

of placental glycine production via SHMT is methylene tetrahydrofolate, which could be involved in a variety of methylation reactions within the placenta.[179] These examples of placental-fetal interorgan shuttling of amino acids, and particularly between the fetal liver and placenta, are now recognized to be an important and unique aspect of fetal metabolism.

FETAL HINDLIMB METABOLISM OF AMINO ACIDS

Several laboratories have studied the amino acid uptake by the fetal ovine hindlimb as being representative of the fetal carcass/extrahepatic tissues. Its metabolism has been evaluated under normal, maternal fasting, rhIGF infusions, and fetal euglycemic hyperinsulinemic states.[182–185] Under normal physiologic conditions, the hindlimb of a growing fetus shows a net uptake of both essential and nonessential amino acids from the fetal circulation,[184] which is in contrast to adult hindlimb studies that show a large output of alanine and glutamine.[185] It is theorized that the high amino acid uptake by the fetal hindlimb could be explained by the relatively high nitrogen accretion rate of the fetus.[184] There is a net uptake across the hindlimb of two amino acids that are not supplied by the placenta: glutamate and serine. It is estimated that the net fetal hepatic output could account for the combined uptake of glutamate by the placenta and the hindlimb.[184] Given the large uptake of alanine by the fetal liver, it is interesting that the fetal hindlimb shows no net release of alanine.[185]

Liechty et al.[186] reported a relatively high activity for ketoacid carboxylase activity in fetal skeletal muscle. In pregnant sheep, after fasting, there is an approximate fivefold increase in the utilization of glutamine and a twofold increase in the utilization of the BCAAs by the uteroplacental tissues, suggesting a possible interorgan cycle between hindlimb and placenta, with the hindlimb supplying glutamine during the maternal fasted state.[186] Under euglycemic, hyperinsulinemic conditions, fetal lambs were noted to have significantly decreased arterial concentrations of most amino acids, and significantly increased limb uptake of alanine, asparagine, glycine, isoleucine, methionine, and tyrosine, and a decreased uptake of aspartate, but with no significant change in net total nitrogen uptake.[184,186] These studies show that the stimulation of alanine uptake by insulin is opposite to the effect of maternal fasting, suggesting that insulin or IGFs may play a role in regulating an alanine exchange between fetal circulation and nonvisceral

fetal tissues.[184,186]

AMINO ACID TRANSPORT SYSTEMS AND ABNORMAL PREGNANCY OUTCOMES

In several clinical studies, the concentration of amino acids has been observed to be lower in the fetal and maternal plasma of pregnancies that were complicated by FGR,[187–189] suggesting alterations in amino acid delivery. This depression in amino acid concentrations occurs regardless of whether fetal concentrations were determined at the time of delivery or many weeks prior to delivery. Additionally, it has also been found that lower amino acid concentrations are found in FGR pregnancies even if the fetus had normal fetal heart rate and velocimetry measurements,[187,188] suggesting that this may antedate other clinical pathologic findings.[190]

Studies in human FGR demonstrate that System A activity may be impaired.[191,192] An in vitro study utilizing MVM vesicles from the placentae of appropriate for gestational age (AGA) and small for gestational age (SGA) babies demonstrated markedly lower activity (by 63%) of the A system transporters in the SGA compared to the AGA membrane vesicles, suggesting a positive association between fetal growth and System A activity.[192,193]Further, studies with placental villous fragments from pregnancies with SGA infants with and without maternal preeclampsia and from uncomplicated and preeclamptic pregnancies with normal-sized infants have shown there is a reduced uptake of amino acids in SGA pregnancies without preeclampsia.[191]

Inhibition of System A transport in rat pregnancies has been associated with slight decreases in fetal weight, demonstrating a potential role for System A transport in maintaining normal fetal growth.[192] Of particular interest is that imprinted genes control the supply of nutrients to the fetus, and, in the mouse, the System A isoform, SNAT2 (Slc38a4), has been identified as being an imprinted gene. In studies utilizing the placental-specific Igf2 transcript (P0) knockout, placental growth is compromised, though fetal demands are met presumably through an up regulation of transporter genes Slc2a3 (glucose transporter) and the imprinted SNAT during mid-gestation, though intrauterine growth retardation (IUGR) still results near term.[194–196], Interestingly, when fetal demands for nutrients are removed through removal of the fetal Igf2, the up regulation does not occur, providing evidence of regulation of placental transport activity via fetal growth demand genes. Both the Igf2 and Slc38a4 are paternally

expressed, and this interaction is seen as a display of paternally inherited genes maximizing extraction of maternal nutrients.[194–196]

In human FGR vesicle studies the TAUT protein expression is unaltered,[117] though the transport activity of this transporter appears to be reduced.[47] However, it is important to emphasize that vesicle studies have not taken into account the possibility of nonhomogeneity in the placenta for FGR pregnancies. There remains the very real possibility that the proportion of terminal villi to intermediate and stem villi are altered in FGR pregnancies, and, depending on the distribution of any transporter, this maldevelopment could profoundly affect transport in vivo without any changes in transporter expression or activity.

Altered System A, and also Systems X_{AG}^- and y^+ activity, have been reported in maternal protein deprivation induced FGR in rats.[60,197] However, again one must be cautious in extrapolating such studies to humans since protein deprivation in the rat has a profound effect upon maternal plasma amino acid concentrations, a condition not found in human FGR pregnancies. Also, amino acid accretion and utilization of a rat fetus is much greater than the human fetus given the much faster growth rate of the rat fetus, up to 20 times faster near term. With regard to System X_{AG}^- transport, the BM activity of EAAT-1 is reduced in an FGR rat model, which could impact placental glutamate uptake from the fetal circulation,[60] though in human studies, no differences were found in the distribution of the glutamate transporters between control and IUGR placentae.[66]

MVM System y^+ and y^+L activity does not appear to be altered in human FGR,[50] though uterine oxygen tension may impact overall cationic amino acid transport.[127] Additionally, BM transport of lysine is reduced as represented by reduced mediated lysine uptake and a reduced Vmax for the y^+L system,[50] and in pregnancy, array data demonstrate up regulation of System y^+ components.[57] Reductions in the uptake of leucine in both MVM and BM preparations of FGR placentae highlight possible alterations in the L transport system.[50] These changes in BM transport properties could be an important adaptive response by the trophoblast, limiting the back flux of amino acids from the fetal circulation to the placenta. In vivo studies of ovine FGR placental transport have indeed shown a reduced backflux of leucine and threonine from the fetal circulation to the placenta, suggesting that changes in BM function may have occurred.[161] At steady state, the fetal/maternal (F/M) enrichment

ratioof leucine in normal human pregnancies is approximately 0.8, a much higher ratio than the 0.4 ratio in sheep.[23,161,198] However, in both species, this ratio is significantly lower in FGR pregnancies. In the ovine FGR model, the reduction in F/M enrichment ratio was due to a significant reduction in transplacental leucine flux,[161] and that is probably the mechanism in human FGR pregnancies as well. Furthermore, the magnitude of the leucine ratio reduction correlates with a clinical classification of FGR severity based upon a completely different set of clinical data, namely, fetal arterial velocimetry and fetal heart rate data.[190] In addition, recent clinical studies have shown that the leucine and phenylalanine F/M enrichment ratio is significantly lower in human FGR compared to normal pregnancies, and that vesicle transporter activity is also impaired.[23,50,198]

Finally, the observations of differences in amino acid transport activity in the FGR placenta highlight the important point that the activity of transport systems must be considered in conjunction with other contributors to amino acid flux. In studies comparing normal and FGR placentas there are reported reductions in total villous surface area,[135,199] suggesting that morphometric changes contribute to the overall reduction in placental amino acid transport capacity. Thus, at the present time, it appears that both reductions in surface area for exchange and changes in terminal villi/stem villiproportions as well as reductions in specific transporter number and activities are major factors contributing to the reduction in amino acid transport in FGR pregnancies.

While there is a developed knowledge on amino acid transport changes in FGR pregnancy, there is a large deficit in our understanding of how these systems are modulated in pregnancies associated with obesity. Studies show that a maternal high-fat diet in pregnant rats causes up regulation of placental nutrient transport (GLUT1 and SNAT2), resulting in fetal overgrowth.[200] Much of the work concerned with placental function and obesity is currently focused around System A. Regulation of System A activity in obesity is associated withincreased cytokine levels and altered maternal adiponectin levels. Physiological concentrations of the proinflammatory cytokines, IL-6, and tumor necrosis factor-α, in cultured human primary trophoblast cells, are found to stimulate the activity of amino acid transporter System A, but not System L,[100] while adiponectin appears to negatively impact insulin-stimulated System A amino acid transport.[201] Also associated with obesity are elevated circulating fatty acids. Oleic acid in culture is found to significantly

upregulate trophoblast System A activity.[106] Further, studies suggest that obesity associated activation of insulin/IGF-I and mTOR signaling pathway also play a pivotal role in the activation of System A,[97] highlighting that fetal overgrowth associated with obesity is the result of a complex interaction of factors culminating in the increased activity of System A. Many of these studies established that System L was unaltered in these situations,[97] opening the question of how other amino acid transport systems are impacted in obesity.

NEONATAL IMPLICATIONS OF FETAL AMINO ACID SUPPLY AND METABOLISM

One may ask how studies of amino acid nutrition and metabolism during fetal life can contribute to our approach to optimal nutrition for very premature infants in a neonatal intensive care unit. First, it is important to recognize that normal fetal development and postnatal development are vastly different biologic states. Not only are there profound endocrine changes triggered by delivery and its associated separation from the placenta, but also the interorgan cycling of amino acids between the fetal organs and placenta is abruptly terminated. However, certain principles of amino acid metabolism during early development still apply. To summarize, during fetal development, amino acids are taken up in amounts that far exceed their requirements for growth.[7,9,11,18,202] The excess amino acid intake leads to a high rate of amino acid oxidation and a relatively high rate of urea production.[15] A second general characteristic is the absence of gluconeogenesis. The accommodation to this leads to a hepatic production and release of serine and glutamate that reduce the CO_2 production requirements of the fetal liver just as glucose production does in postnatal life. It is important to emphasize that the requirements of amino acids change quite markedly with increasing gestational age, and also depend upon whether there has been normal or abnormal fetal growth. In the normal term newborn, the rate of net protein accretion in utero is quite low, with fat accretion dominating growth. In FGR fetuses with relatively mild FGR, there are reduced plasma amino acid concentrations reflecting the reduced placental supply. In severe FGR, with virtually no fetal growth, plasma concentrations are not affected. There may also be vascular changes, which lead to hepatic injury.

The delivery of optimal nutrition to the small premature infant is a critical factor to the infant's overall care.[203–205] Very premature infants

have been delivered before they have gone through the phase of in utero development associated with rapid accretion of fat depots and glycogen stores. Preterm infants are born at gestational ages associated with rapid accretion of protein in utero. This has led to a neonatal nutritional approach, which emphasizes the early provision of amino acids to very preterm babies.[204] It should be emphasized, however, that this makes an assumption of good liver perfusion and the absence of any prenatal liver injury. Neither of these conditions necessarily applies to an individual newborn in the immediate neonatal period. The best guideline for assessing the nutritional status of the low-birth weight infant is not clear. However, one approach would include achieving a postnatal growth that approximates the in utero growth rate of a normal fetus.[206] By this guideline, the intrauterine accretion rate of amino acids becomes a reference point defining the minimal requirements in the neonatal period. As delineated in the previous discussion, the mammalian fetus utilizes the circulating maternal free amino acid pool as its primary nitrogen source for growth with certain conspicuous exceptions. Since amino acid oxidation is linked to hepatic gluconeogenesis in postnatal life, and since gluconeogenesis is a requirement for postnatal adaptation, one would expect amino acid oxidation to be sustained during postnatal development, significantly increasing amino acid requirements. For the premature infant, the primary sources of nitrogen may be obtained from a variety of sources including that obtained from parenteral nutrition, or human breast milk, or premature infant formulas. Current nutritional management for preterm and FGR infants aims at early provision of amino acids.[204,205]

Recommendations for the quantity of protein delivery include 3.6–3.8 g/kg/d gross protein intake for the stable growing infant at less than 27 weeks gestation and less than 1000 g, and 3.0–3.6 g/kg/d for the 1000- to 1750-g infant at 28- to 34-week gestation. Although the exact quantity is debated (i.e. European guidelines versus American guidelines), it is generally accepted that the stable growing low-birthweight infant requires, on the average, a parenteral amino acid intake of 3.0 g/kg/d to ensure accretion of nitrogen at the intrauterine rate of approximately 300 mg/kg/d. This amino acid intake plus an energy intake of 80–100 kcal/kg/d results in a weight gain that approximates the intrauterine rate of 15 g/kg/d.[207] However, the studies of the fetal circulation in FGR pregnancies makes it clear that the general recommendations should be used with caution in newborns of any weight or gestational age when there is evidence of circulatory compromise in utero. A high carbohydrate and relatively low nitrogen intake is prudent in these circumstances. Certainly, if a high

nitrogen intake is given to such infants, there should be an assessment of ammonia and urea levels as well as measurement of amino acid concentrations to be sure the nitrogen load is not compromising the infant. This caution reflects the fact that there are still no ideal approaches to assess both the quality and quantity of amino acids provided as protein in milk feedings to low-birth-weight infants. The assumption that the accretion of nitrogen should approximate that of a fetus of comparable gestational age has not been adequately tested. Given the radically different environmental conditions of the preterm infant versus the fetus and the marked endocrine changes imposed by delivery of the infant and loss of the placenta, this untested assumption should be viewed with a healthy skepticism. Only long-term follow-up studies of preterm infants fed differently will clarify what nutritional approach is best. Breast milk provides a large array of compounds not included in formula feedings. Some of these compounds such as glycoproteins and peptides contain amino acids. Owing to the instability of glutamine it is currently omitted from parenteral nutrition solutions and infant formulas. Glutamine has recently been found to be an important metabolic fuel for lymphocytes[208,209] and intestinal epithelial cells,[210] and is supplied to the ovine fetus in large amounts throughout gestation.[149]

It has already been demonstrated that formula-fed, very-low-birth-weight infants whose weight gain was comparable to that of a normal fetus retained the same amount of protein (≈ 1.9 g/kg/d), but accumulated fat at approximately three times the rate of the fetus. This indicates that the body composition of the premature infant will differ from that of the comparable placentally nourished fetus.[211] How this will impact on long-term growth and neurodevelopment is unclear and a continuing discussion point.[212,213] It should also be pointed out that the term “amino acids” applies to a group of compounds with vastly different transport properties and metabolic properties. It has already been shown in animal studies that if the concentrations of all amino acids are increased in the maternal circulation, the supply of some amino acids to the fetus is significantly reduced despite the increased maternal concentration through the impact of competitive inhibition.[214]

As the complex interplay among fetus, placenta, and maternal dietary supply of amino acids becomes increasingly clear, it is hoped that this information can be used to understand more completely the remarkable process of fetal growth and maturation. This, in turn, will then be invaluable information in the further modification and design of feeding regimens for premature infants in order to optimize growth and long-term

neurodevelopment.

Human Milk: Nutritional Properties

29

Marcia H. Monaco, PhD Sharon M. Donovan, PhD, RD

HEALTH BENEFITS OF HUMAN MILK FOR THE INFANT

Human milk provides nutrients with high bioavailability and in sufficient qualities to support the needs of the rapidly growing human infant, and is defined as the "normative standard of infant feeding" by the American Academy of Pediatrics (AAP).[1] As such, the recommended dietary intakes for infants in the first six months of life are based on the nutrient analysis of human milk and average volumes of milk consumption by healthy, full-term, exclusively breast-fed infants.[2] The specific nutrient requirements of the term infant are discussed further in Chapter 36. Human milk also is recommended for the preterm, low-birth-weight (LBW) infant due to the associations between human milk feeding and reduced incidence of necrotizing enterocolitis[3] and improved IQ scores.[4] However, the nutrient content of either term or preterm human milk is insufficient to meet the needs of infants less than 1500 g and should be supplemented with a human milk fortifier for optimal nutrition.[1,5] The specific nutrient requirements of the LBW infant are presented in Chapters 32 and 33.

In addition, human milk contains bioactive factors whose functions extend beyond providing essential nutrients and energy and appear to facilitate the optimal transition of the infant from intra- to extrauterine life.[6] Components in human milk actively protect the infant from pathogenic infection and facilitate the establishment of the microbiota, the latter of which is required to activate the mucosal immune system.[7]

Indeed, clinical and epidemiological data provide strong evidence that human milk feeding decreases the incidence and/or severity of diarrhea, respiratory and urinary tract infections, otitis media, and necrotizing enterocolitis.[1] This protection likely is mediated through the immuno protective proteins, lipids, and carbohydrates (oligosaccharides) in human milk that exert antibacterial and antiviral activities[7] (see Chapter 30 for additional discussion of protective properties of human milk).

In addition, there is evidence that breastfeeding confers longer term risk reduction for autoimmune diseases. Exposure to beneficial components in human milk that promote the development of the immune system and/or a lack of exposure to stimuli that would trigger an inappropriate immunologic response in genetically predisposed individuals have been proposed as mechanisms underlying the reduced risk of developing autoimmune diseases,[8,9] although the relative contributions of these two effects are unknown. Breastfeeding is associated with lower risk of celiac disease[10] when the introduction of gluten occurs concomitantly with breastfeeding and insulin-dependent diabetes mellitus.[9] Evidence for prevention of atopic eczema,[11] asthma,[12] wheezing,[13] and inflammatory bowel diseases[8] is less conclusive and further rigorous research is needed to elucidate the interaction between the infant's genetic predisposition and breastfeeding in modulating the risk of these diseases. As dietary antigens can cross the placenta, as well as pass into human milk, pediatricians have recommended maternal antigen avoidance during pregnancy and/or lactation as a strategy to prevent or treat atopic diseases in children at high risk for developing atopic diseases. A systematic review of the randomized or quasi- randomized trials found that antigen avoidance during pregnancy or lactation did not substantially reduce the risk of the child developing atopy and may adversely affect maternal and fetal/infant nutritional status and, thus, is not recommended.[14] The benefits of antigen avoidance diets during lactation on the development and severity of atopic eczema are equivocal at best, and trials with large sample sizes are needed in this area.

Strong evidence indicates the association of breastfeeding with higher cognitive development compared to formula feeding.[4,15] Breastfeeding for more than four months was associated with a 4.3 points augmentation in the Bayley mental developmental index of 2-year-old, even after adjusting for confounding factors (socioeconomic, parental IQ, etc.).[15] The greatest benefit was gained by preterm versus term infants, particularly those who received human milk for at least six months.[16] In one study, duration of breastfeeding, the infant's gestational week at birth, and maternal milk

docosahexaenoic acid to arachidonic acid ratio (DHA-to-AA) yielded a three-factor model that explained 76% of the variation in total IQ ($P < 0.001$).[17]

Recent systematic meta-analysis and reviews support an inverse relationship between breastfeeding and the risk of pediatric overweight, though the extent of this relationship tend to decrease when adjustments for confounding factors, such as maternal education, maternal body mass index (BMI), socioeconomic status, and maternal smoking, among others, are taken into consideration.[18] Breastfeeding for greater than four months is associated with an approximately 20%–50% reduction in the risk of pediatric overweight[19]–[21] and each month of prolonged exclusive breastfeeding was associated with a weight gain reduction of approximately 100 g after adjustments for infant and maternal factors.[22] Moreover, breastfeeding for greater than 25 days was associated with a 14% decrease in fat mass measured by dual-energy X-ray absorptiometry (DXA) in 16-year-old adolescents.[23] An additive interaction was observed between maternal pre-pregnancy BMI and breastfeeding, in that 2- to 14-year-old children of obese mothers (BMI ≥ 30) who were never breast-fed had a 6.1-fold greater risk (95% confidence interval 2.8, 13.1) of being overweight (BMI ≥ 95th percentile) than children of normal-weight mothers who were breast-fed.[19] Even in women who were overweight (BMI ≥ 25) or had diabetes, breastfeeding was protected against the development of overweight in their 9- to 14-year-olds.[20] Taken together, these latter two studies provide compelling justification to promote breastfeeding in all mothers, particularly those with high BMI. However, several recent studies suggest that overweight women experienced delayed initiation of lactation and may require additional measures of lactation support.[24] Additional information on breastfeeding can be found in Chapter 31. Reducing the prevalence of childhood overweight by breastfeeding may exert long-term protection against the development of type-2 diabetes. A recent study analyzing data on over 10,000 subjects from five prospective studies conducted between 1969 and 1990 in low- and middle-income countries failed to find any association between duration of breastfeeding and development of diabetes adult in adulthood.[25] It is clear that more studies are needed to define the impact of breastfeeding on the onset of adult type 2 diabetes.

POLICY RECOMMENDATIONS AND

BREASTFEEDING TRENDS

Breastfeeding is the preferred form of nutrition for the human infant and is recommended by national and international health organizations and pediatric societies. AAP recommend exclusive breastfeeding for the first six months of life,[1] but strongly supports the continuation of breastfeeding for at least the first year of life and beyond, as long as mutually desired by the mother and child, with the addition of complementary foods at 6 months of age.[1] The timing and composition of complementary feeding are discussed further in Chapter 35.

Breastfeeding rates have risen slowly but steadily over the past decade and, in 2009, approximately 76% of infants received some human milk in the early postpartum period.[26] The breastfeeding rates decrease to 47% and 25% at 6 and 12 months postpartum, respectively. Breastfeeding initiation rates (approximately 76.9%)[26] are near the Surgeon General's Healthy People 2020 goal of 81.9%[27] and it was estimated that if breastfeeding were to continue to increase at the current rate (approximately 2%/y), inhospital breastfeeding in the United States should meet or exceed the Healthy People 2020 goal. However, breastfeeding rates at 6 and 12 months postpartum are still lower than the Healthy People 2020 goals of 60% and 34%, respectively,[27] and these goals will likely not be met in all subgroups in the population if current trends persist. Maternal age, education, race/ethnicity, income, geographic location, and participation in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) affected breastfeeding rates, with rates being highest for white non-Hispanic, older, college-educated mothers.[28] Using data collected in the 2007 National Immunization Survey, breastfeeding initiation among WIC participants was nearly 17% lower than nonWIC participants, and breastfeeding duration differed significantly between these two groups (6.7 vs. 8.2 months, respectively).[29] Thus, for Healthy People 2020 goals to be achieved, effective strategies must be developed to promote breastfeeding in young, less educated mothers and those participating in WIC.[30] In 2011, the Surgeon General issued a Call to Action to support breastfeeding that described specific steps people can take to participate in a society-wide approach to support breastfeeding mothers and babies. This approach will increase the public health impact of everyone's efforts, reduce inequities in the quality of health care that mothers and babies receive, and improve the support that families receive in employment and community settings.[30]

ASSESSING THE GROWTH OF BREAST-FED INFANTS

It has long been recognized that the patterns of linear growth, weight gain, and body composition during the first year of life differ between breast-fed and formula-fed infants[31] and even between infants who are breast-fed for short duration versus longer term exclusive breastfeeding.[32] A recently published systematic review (15 studies) and meta-analysis (11 studies) examined the pattern of changes in body composition of healthy breast-fed and formula-fed infants.[31] Fat-free mass, fat mass, and % fat mass were determined by a variety of methods (i.e., total body potassium determination, total body electrical conductivity, DXA, MRI, air displacement plethysmography, and isotope dilution). Formula-fed infants had higher fat-free mass at 3–4 months (mean difference + 130 g), 8–9 months (+290 g) and 12 months (+300 g), where as fat mass was lower at 3–4 months (−90 g) and 6 months (−180 g) than breast-fed infants. Conversely, at 12 months, formula-fed had higher fat mass (+290 g) than breast-fed. This particular review did not include infants older than 12 months, however, others have reported that any difference in growth trajectory between formula-fed and breast-fed infants detected in the first year of life disappeared after 24 months postpartum.[33] Importantly, head circumference does not differ between breast-fed and formula-fed infants.[34]

Assessment of growth in children is important for monitoring health status. There are several growth charts available for assessing the adequacy of children's growth, but it is recommended that the WHO child growth charts, which were generated from anthropometric data collected from approximately 8500 children in Brazil, Ghana, India, Norway, Oman, and the United States through the WHO Multicenter Growth Reference Study be used for children under 2 years of age.[35] The growth standards are available on the Internet (http://www.who.int/childgrowth/standards/en). Importantly, the WHO standards demonstrated that breast-fed infants worldwide, who are raised in healthy environments, exhibit similar patterns of growth.[35] More recently, WHO released growth velocity standards for weight, length, and head circumference. The standards cover from birth to 2 years of age, and are based on another multi country study involving breast-fed infants and young children from six separate geographical regions.[36] Growth velocity curves are considered a superior quantitative measure of growth compared to attained size (weight or length) for age. Furthermore, monitoring growth

velocity supports early detection of abnormal growth patterns and allows for timely clinical intervention.[36]

In summary, the WHO international growth standards are based on exclusively breast-fed infants and represent the growth patterns of infants following current AAP and WHO recommendations.[1] Whichever growth charts a practitioner chooses to use, it should be kept in mind that growth charts are tools that contribute to forming an overall clinical impression of the child and should not be used as a sole diagnostic instrument.

PHYSIOLOGY OF LACTATION AND MILK PRODUCTION

Initiation of Lactation

The lactation cycle consists of four phases: mammogenesis, lactogenesis, galactopoiesis, and involution. Mammogenesis is a long-term process that is hormonally stimulated during adolescence, with further development during pregnancy and terminal differentiation during lactation.[37] Lactogenesis is associated with the expression of lactation-specific genes in mammary secretory epithelial cells and is divided into two stages.[37] Lactogenesis I occurs during mid-pregnancy and represents the initiation of the unique synthesis capacity of the mammary gland. Lactogenesis II occurs just before or at the time of parturition and is associated with a drop in circulating progesterone and estrogen concentrations, sustained prolactin secretion, the initiation of copious milk secretion, and marked changes in milk composition.[37] Colostrum, the first milk produced following delivery, is characterized by high concentrations of total protein, immunoglobulin, sodium and chloride, and low concentrations of lactose, potassium, glucose, and citrate.[37] The increase in lactose and decrease in sodium and chloride concentrations signal closure of paracellular pathways at day 1–2 postpartum.[37] From days 2–4 postpartum, increased milk citrate, free phosphate, glucose and calcium concentrations, and decreased milk pH are observed. Changes in one or more of these milk constituents are used to identify the onset of lactogenesis II, which typically occurs between 30 and 40 hours postpartum in term mothers. Premature delivery,[38] cesarean delivery,[39] and insulin- dependent diabetes mellitus[40] have been reported to suppress or delay lactogenesis II and detrimentally impact the successful establishment of lactation. Women at risk for delayed initiation of lactation often are advised to use breast pumps to

stimulate milk production. For example, in a recent study, mothers of very low-birth-weight infants born prematurely (<32 weeks of gestation) were randomized to initiate milk expression either within 60 minutes of birth or one to six hours following delivery. Women who started milk expression within one hour of birth had increased milk volume and experienced decreased time to onset of lactogenesis stage II.[41] This study suggests the timing for milk expression may be critical for milk production and prolonged lactation. Chapman and colleagues[42] conducted a randomized clinical trial to assess the effectiveness of pumping on early milk transfer and duration of breastfeeding among primiparous women after cesarean delivery at term. Unexpectedly, breast pumping between 24 and 72 hours after delivery did not improve milk transfer in the first 72 hours postpartum and appeared to negatively affect overall breastfeeding duration.

Even among highly educated, motivated women who delivered at term, nearly 50% of mothers experienced suboptimal breastfeeding behaviors (SIBB) on the day of delivery, which declined to 22% and 14% by day 3 and 7 postpartum, respectively.[43] Primiparity, cesarean delivery, prolonged stage II labor (>1 hour), birth medications, and infant status at birth (low APGAR score) were associated with SIBB, suggesting that birth-related events can detrimentally impact the initiation of lactation.[42] Flat or inverted nipples, the use of nonhuman milk fluids within the first 48 hours postpartum and pacifier use were also risk factors for SIBB.[42] Thus, lactation success can be improved by proactively addressing modifiable factors during delivery and the early postpartum period and all breastfeeding mothers should be evaluated for SIBB at 72–96 hours postpartum.[43] Dewey and colleagues[43] also identified high maternal BMI (>27) as a risk factor for SIBB. Subsequent studies confirmed that pre-pregnancy BMI was negatively associated with the onset of lactogenesis II[24] and overweight or obese mothers breast-fed their infants for a shorter duration than normal-weight women.[24,44] There may be a physiological basis for the lower lactation success in that overweight and obese women had a reduced prolactin response to suckling in the first week postpartum.[44]

Milk Production

The volume of human milk produced can be assessed by “test weighing” a breastfeeding infant before and after each feeding for a 12 or 24 hours period, or by the deuterium oxide dilution method. A systematic review of

22 studies found that mean human milk intake of exclusively breast-fed infants increased approximately 20–30 g/mo from 699 g/d at 1 month, to 731, 751, 780, 796, and 854 g/d at months 2–6, respectively.[33] The greatest changes in milk volume occur in the first week after birth. A recent meta-analysis on 25 published papers indicated changes in milk consumption from 22 ± 4.2 ml/d on day 1 postpartum to 100 ± 22, 285 ± 40, 384 ± 17, 457 ± 21, and 495 ± 33 mL/d on days 2–7. By day 14, milk intake was approximately 1.4-fold higher than day 7.[45] A cross-sectional study by Kent and colleagues[46] monitored 775 breastfeeding episodes of infants aged 1–6 months and assessed milk production by test weighing and the extent of breast emptying by milk fat content. In that study, infants nursed on average 11 ± 3 times/d (range: 6–18), with an inter-feeding interval of 138 ± 43 minutes (range 4–658 minutes) and 64% of infants breast-fed 1–3 times per night.[46] There were no differences in breastfeeding frequency with age or between girls and boys; however, the volume per feeding increased with age and was greater in male than female infants.[46] Infants consumed 76.0 ± 12.6 g milk (range 0–240 g) per feeding and overall 24-hour milk production was 788 ± 169 g/d (range 440–1365 g/d).[46] Interestingly, they found that milk production differed between breasts, with the right breast producing on average nearly 90 g/d more than the left breast (443 vs. 356 g/d).[46] Interestingly, for 53% of the breastfeeding episodes, the contents of one breast were sufficient to satisfy the infant for at least one hour and, on average, only 67.3 ± 7.8% (range 0–100%) of the available milk in the breast was removed at each feeding. These data suggested that both breasts do not need to be offered at each feeding episode, nor does a breast need to be fully drained at every feeding to maintain adequate milk production.[46] The authors concluded that breastfeeding mothers should be encouraged to feed their infants on demand rather than conform to average recommendations that may not be appropriate for that "mother–infant dyad."[46]

DYNAMIC NATURE OF HUMAN MILK COMPOSITION

The nutrient composition of human milk is dynamic and changes in response to mammary gland physiology (lactogenesis, involution) and maternal diet.[47] Milk composition also differs between mothers who deliver prematurely versus at term, which, in part, may reflect the degree of mammary gland maturation at delivery.[48] How stage of lactation and

maternal diet impact the content and composition of individual classes of nutrients will be discussed in depth in subsequent sections of this chapter.

In general, the composition of human milk varies throughout the course of lactation.[47,48] Colostrum, the first secretions produced by the mammary gland, persists from birth to five days postpartum. Colostrum is a low-fat, high-protein fluid that is rich in immune protective components. The milk produced over the next nine days is termed "transitional milk" and is most variable in its composition as women transition at different rates from lactogenesis II to galactopoiesis.[47] Typically, by 15 days postpartum, "mature" human milk is produced and its composition is relatively stable until weaning.[47,49] At weaning, minor changes in milk protein, lactose, chloride, and sodium concentrations were observed when milk volume declined to less than 400 mL/d. Although considerable information is available regarding changes in human milk composition in early lactation[47,49] or at weaning, less is known about the effect of sustained extended lactation (>6–12 months) on the nutrient content of human milk, particularly for micronutrients.[50] Karra and colleagues[50] reported that, zinc, calcium, and vitamins B_6 and C tended to decrease between 7 and 25 months postpartum, where as folate concentrations remained constant and magnesium levels only decreased after 18 months of lactation. Lactose, protein, and sodium increased slightly, but significantly after 10 months of lactation. These decreases in milk nutrient content between 7 and 25 months of lactation may have little nutritional significance for the infant as the mean number of breast feedings declined from 6 to 2 to 3 per day over this period and infants at this age are consuming other foods in their diets.

In addition, milk composition changes markedly within a single feeding. The first milk (foremilk) released by the mammary gland is low in fat and the fat content increases throughout the feeding and is highest in the "hindmilk."[49] Comparing paired fore- and hind milk samples collected from the same mother, protein and lactose contents were similar, where as the fat content of hind milk was two- to threefold higher and provided approximately 25–35 kcal/100 mL more energy than foremilk.[49] These variations in human milk composition within a feeding must be taken into account when obtaining samples for compositional analysis. The most accurate determination will be obtained when the complete contents of the breast are expressed and mixed prior to taking a sample for analysis.

BIOCHEMICAL COMPOSITION

Nutrients in human milk are contained in discreet compartments that reflect their chemical characteristics as well as their processing and packaging during milk synthesis. Most water-soluble nutrients are present in the aqueous phase (whey), which represents the largest compartment of human milk.[47] Casein proteins are present in milk as a colloidal dispersion and fats and fat-soluble components are present in an emulsion of milk-fat globules surrounded by a milk-fat globule membrane.[47] The physical compartmentalization of nutrients in human milk differs from infant formulas and likely contributes to the dissimilarities in nutrient bioavailability between the two fluids.

Mature human milk is approximately 88% water with a specific gravity of 1.030. The osmolarity of human milk is approximately 286 mOsm/L compared to 185–374 mOsm/L in infant formulas.[51] There is no evidence that healthy appropriate birth weight[52] or LBW[53] infants require additional water, even in hot climates. The total solids in human milk are approximately 124 g/L, of which 70 g/L is carbohydrate, 40 g/L is fat, 10 g/L is protein, and 2 g/L is mineral ash.[47,54] In comparison, bovine milk contains three-times more protein (35 g/L) and mineral ash (7 g/L), less lactose (9 g/L) and similar amounts of total solids (128 g/L), fat (37 g/L), and water (87%).[47,54]

Energy Content

The energy content of human milk can be directly measured by bomb calorimetry or approximated from the protein, carbohydrate, and fat content of milk multiplied by their Atwater values.[55] Typically, mature human milk contains between 2730 and 2940 kJ/L (650–700 kcals/L) (Table 29-1).[45,47,55] The energy content of colostrum (days 2–7 postpartum; 571 ± 80 kcals/L) and transitional (days 8–20 postpartum; 629 ± 76 kcals/L) human milk is lower than mature milk (≥21 days postpartum; 642 ± 36 kcals/L).[55] Milk caloric density, calculated as the sum of the energy provided by each macronutrient, was 6%–10% higher than that obtained by bomb calorimetry of the same milk samples, suggesting that the former method may overestimate the energy content of human milk.[55] In addition, it is important to keep in mind that some human milk proteins[56] and oligosaccharides[57] are resistant to digestion in the neonatal gastrointestinal tract. Therefore, bomb calorimetry may also overestimate the bio available energy content of human milk.

Carbohydrate

The predominant macronutrient present in human milk is carbohydrate in the form of lactose and oligosaccharides.[47,54] Lactose, the disaccharide of glucose and galactose, is readily digested by nearly all infants, where as oligosaccharides are non digestible and play a number of functional roles in the infant.[54]

Lactose and Glucose

After water, lactose is the most prevalent nutrient in human milk, with an average concentration of 70 g/L (67–76 g/L) in mature human milk (Table 29-1).[45,47] The lactose content of colostrum is lower than mature milk,[45] although colostrum is rich in oligosaccharides.[58] All oligosaccharides contain lactose at their reducing end,[58] therefore, the amount of free lactose in human milk may be overestimated if the analytical method used to quantify lactose cleaves the lactose from oligosaccharides. Lactose is the major osmol in human milk and its concentration is positively correlated with milk yield. The concentrations of lactose and alpha-lactalbumin (α-LA) in milk also are positively correlated, because lactose is synthesized by the actions of α-LA and galactosyltransferase. Lactose is one of the most stable constituents in human milk and varies little after lactation is established.[49,50] Human milk contains very low levels of free glucose[59] (Table 29-1) and other glucose metabolites,[59] which are likely of little nutritional significance to the infant. Glucose concentrations were not higher in the milk of insulin- dependent diabetic (IDDM) mothers.[59] Glucose normally rises in milk with the onset of lactogenesis II[59]; however, this rise was delayed by 1–4 days in IDDM mothers, associated with compromised initiation of lactation.[59]

TABLE 29-1 Energy and Macronutrient Composition of Colostrum and Mature Human Milk

Constituent (per L)	Colostrum	Mature Milk
Energy (kJ)[a]	2244	2729
Total carbohydrate (g)	26–76	50–83
Lactose (g)	30–50	67–70
Oligosaccharides (g)	22–24	5–15
Glucose (g)	0.2–1.0	0.2–0.3
Total lipid (g)	10–27	28–49
Triglyceride (g)	14.5–19.5	34–47

Fatty acids (g)	13–17	30–42
Cholesterol (g)	0.2–0.3	0.1–0.2
Cholesteryl esters (g)	0.05	0.01
Phospholipids & sphingolipids (g)	N.R.[b]	0.25–0.30
Total nitrogen (g)	3.0	1.9
Nonprotein nitrogen (g)	0.5	0.45
Protein nitrogen (g)	2.5	1.45
Total protein (g)	14–65	8–21
Casein (g)	3.8	3–5
β-casein (g)	2.6	3–4
κ-casein (g)	1.2	1–2
Whey proteins (g)	11–15	5–6
α-lactalbumin (g)	3.6	2–3
IgM (g)	0.02	0.01
IgG (g)	0.01	0.05
Lactoferrin (g)	3.5	1–3
Lysozyme (g)	0.1–0.2	0.1
Secretory IgA (g)	2.0	0.5–1.0
Serum albumin (g)	0.4	0.3

[b]Data not reported

Oligosaccharides

Human milk is unique in that it contains a diverse array of highly complex oligosaccharides (HMOs), which comprise the third largest component in human milk.[54,60] Oligosaccharide concentrations in human colostrum and mature milk are 22–24 g/L and 12–14 g/L, respectively[54] (Table 29-1). Over 200 separate forms of acidic or neutral HMO have been described in human milk and the composition is influenced by maternal genetics.[58,60] These oligosaccharides are formed by the elongation of lactose with galactose in (Gal) β-1,3 or β-1,4 linkages, or *N*-acetyl glucosamine (GlcNAc) in a β-1,3 linkage to form the two core neutral oligosaccharides, lacto-*N*-tetraose (LNT, Galβ-1, 3GlcNAcβ-1, 3Galβ-1, 4Glc) and lacto-*N*-neotetraose (LNnT, Galβ-1, 4 GlcNAcβ-1, 3Galβ-1, 4Glc), respectively.[60] More complex HMOs then are formed by the addition of fucose and sialic acids (SA),[60] the latter of which are a subset of the nine-carbon sugar, neuraminic acid. The *N*-acetylated form, *N*-acetylneuraminic acid (Neu5Ac; NANA), is the most predominant form and the only one

synthesized in humans.[61] The SA residue is always found at the non reducing end of the oligosaccharide and is attached either by α-2, 3 or α-2,6 linkages to galactose or *N*-acetylgalactosamine (GalNAc).[61]

Many neutral HMOs contain fucose (Fuc) on the non reducing end.[54] These HMOs contain antigenic determinants of the Lewis blood group and/or secretor systems[62] and are synthesized by one of three fucosyltransferases (FTs) that are not uniformly distributed in the population.[58,60] The "secretor" or "nonsecretor" status of a mother is characterized by the presence of FT II activity; nonsecretor mothers have two inactive copies of the gene.[62] FT II catalyzes synthesis of α-1-2 fucosylated oligosaccharides, such as 2'-fucosyllactose (2'-FL, Fuc α-1, 2Galβ-1, 4Glc) and lacto-*N*-fucopentaose (LNF-I, Fucα-1, 2Galβ-1, 3GlcNAcβ-1, 3Galβ-1,4Glc).[62] The other fucosylated HMOs include the 3'-FL derivatives (Gal β-1, 4[Fucα-1, 3]Glc), which are synthesized by several FTs, and difucosyllactose (DFL), which contains both α-1, 2 and α-1, 3 linages (Fucα-1, 2 Gal β-1, 4[Fucα -1,3]Glc).[62] Analysis of the neutral oligosaccharide composition of human milk samples collected from over 400 women living in 10 countries demonstrated the presence of structures based on LNnT and LNT in all samples, where as fucosyloligosaccharides were not uniformly expressed in all women.[62] For example, 100% of the milk samples from women in Mexico contained 2-FL, where as only 46% of the samples from the Philippines contained 2-FL.[62]

HMOs are resistant to hydrolysis in the neonatal small intestine.[57] As a result, structurally intact HMO are absorbed and excreted in the urine and feces of preterm[63] and term[64–66] infants. Obermeier and colleagues[64] orally administered ^{13}C-galactose to lactating women to assess the degree of utilization of dietary carbohydrates for lactose and oligosaccharide synthesis. Approximately 7% of the oral dose (2 g) of ^{13}C-galactose was incorporated in lactose and neutral oligosaccharides within 8 hours and isotopically labeled lactose, 2'-FL, LNT, fucosyl-LNT, and DFL[64,65] and other slightly modified metabolites[65] were detectable in the urine of their nursing infants. Oligosaccharides excreted in urine have the potential to act as analogous receptors for viral and bacterial adhesion molecules and prevent urinary tract infections.[67] Within the blood, acidic oligosaccharides inhibit platelet–neutrophil complexes and neutrophil activation.[63] A more complete discussion of the carbohydrate components present in human milk is presented in Chapter 5.

Oligosaccharides are absorbed to a limited extent, with most reaching the large intestine in an intact form, where in they have the potential to exert widespread beneficial effects on neonatal intestinal health and host defense.[58,60] Oligosaccharides are capable of serving as receptors or receptor analogs for enteric pathogens, including viruses, bacteria, and parasites.[60] In addition, they serve as a pre biotic for growth of bifidogenic bacteria[68] and for the generation of short-chain fatty acids (SCFAs).[68] A recent study utilizing pyrosequencing of 16s rDNA determined that the stool of breast-fed infants contained higher amounts of bacteria from the phyla Actinobacteria (e.g., *Bifidobacteria)* and Bacteroidetes, where as formula-fed infants had higher proportions of *bacteria* from the phyla Firmicutes and Proteobacteria.[69] In another study, stool of breast-fed infants contained primarily acetic and lactic acids, with smaller amounts of butyric or propionic acids, suggesting increased amounts of *bifidobacteria*[70]. In contrast, feces of formula-fed infants contained mostly acetic and propionic acids, the latter of which is produced primarily by *Bacteroides* and *Clostridia*. The SCFAs reduce intestinal pH and, subsequently, decrease potentially harmful gut microbiota.[70]

In contrast to human milk, oligosaccharides are negligible in cow milk and cow milk-based infant formulas.[71] Thus, formula-fed human infants are deprived of these unique bioactive components and their addition to infant formulas has been endorsed as a means to decrease the incidence of viral and microbial infections.[58,60,72] Because HMOs are not yet available in sufficient quantities or approved for addition to infant formula, nonhuman milk oligosaccharides, namely galactooligosaccharides (GOS), polydextrose (PDX), and fructooligosaccharides (FOS) are currently added to infant formula.[60] GOS, PDX, and FOS differ structurally from HMO, and are neither fucosylated nor sialylated.[60] Many clinical trials have investigated the use of the these alternative forms of oligosaccharides and, although the results have been promising,[73] expert committees recommend additional research be conducted to define the optimal quantity and type of oligosaccharide, duration of administration and short- and long-term outcomes before recommendations can be made for the use of oligosaccharides in infant diets.[74]

Fat

Fat is second most prevalent class of macronutrients, averaging 15–20 g/L in colostrum and 35–48 g/L in mature milk and representing approximately 45%–55% of the energy content of human milk.[47,75,76]

Triglyceride accounts for nearly all of the fat in human milk (97.5%–98%), with small amounts of phospholipids and sphingolipids (0.7%) and cholesterol (0.5%)[47,75] (Table 29-1). Triglycerides are synthesized within mammary epithelial cells from glycerol and fatty acids, which are either synthesized within the mammary gland or extracted from the maternal circulation through the action of lipoprotein lipase.[76] Maternal plasma lipids are the major source of longer chain (>16 carbon) fatty acids in human milk, where as saturated fatty acids (10–14 carbons) are synthesized de novo within the mammary gland and their proportion increases in women consuming high-carbohydrate or low-fat diets.[76] Maternal diet contributes approximately 30% of the long-chain fatty acids (16:0, 18:0, 18:1*n*9, and 18:2), where as maternal adipose tissue likely contributes the majority of the remaining 70%, including the long-chain polyunsaturated fatty acids (LCPUFAs).[76]

Within the mammary epithelial cell, milk fat is packaged with other lipophilic compounds and secreted into milk as a milk fat globule, which range in size from 0.6 to 46, 0.6 to 11, and 0.7 to 17 μm in colostrum, transitional, and mature milk.[77] Each globule is surrounded by a bipolar milk fat globule membrane (MFGM) that is derived from the mammary apical plasma and mature Golgi vesicle membranes.[77] The MFGM emulsifies the milk fat and contains a number of bioactive lipids, proteins, and carbohydrates, including lactadherin and MUC1, which may play a role in host defense.[77]

Fatty Acid Composition

Fatty acids esterified to glycerol as triglycerides account for 88% of the fat; very little nonesterified fatty acids are present in human milk.[47,75,76] Approximately 43% of fatty acids are saturated, 35% are cis-monounsaturated, 1%–7% are trans-monounsaturated, and 20% are polyunsaturated fatty acids (19% *n*-6 and 1% *n*-3),[78] although these values can be markedly influenced by maternal diet[47,75] and, to a lesser degree, by stage of lactation.[75,78] For example, the percentage linoleic acid can vary from 1% to 45% of total fatty acids in milk.[47,75] Although 160 different fatty acids have been identified in human milk, the predominant fatty acids are palmitic ($C_{16:0}$; 22%), stearic ($C_{18:0}$; 7%), oleic ($C_{18:1n-9}$; 34%), and linoleic ($C_{18:2}$; 8%) acids (Table 29-2).[47,75,78–80] Digestion and absorption of fat in human milk is more efficient than fat in infant formula. One mechanism may be the presence of bile salt-stimulated lipase (BSSL)

in human milk, which is complementary to pancreatic lipase.[79] Another potential explanation is that human milk triglycerides contain palmitic acid primarily in the sn-2 position, where as infant formula fat blends contain palmitic acid primarily in the sn-1 and sn-3 positions.[79] Pancreatic lipase selectively hydrolyzes triglycerides in the sn-1 and sn-3 positions, producing two free fatty acids and a monoglyceride. Human infants efficiently absorb the 2-monopalmitin, produced during human milk fat digestion, where as free palmitate may form soaps with calcium and be lost in the feces.[79]

Mean values (range) adapted from References 78–82,84–86.

Human milk contains relatively low concentrations of SCFAs (C_4-C_8), but significant amounts of the *n*-3 and *n*-6 LCPUFA AAIC20:4*n*6) and DHA (C22:6*n*3) (Table 29-2). The AA content of human milk averages 0.3–0.6 wt% and is relatively constant worldwide. In contrast, the DHA content of human milk can vary sixfold (< 0.1–1.0 wt%) and reflects maternal DHA intake.[81] Studies indicate that the LCPUFA content of milk produced by mothers delivering prematurely to be greater than that in milk

produced by mothers delivering at term.[82] The LCPUFA levels in neonatal plasma, erythrocyte membranes, neural, and retinal tissues are determined primarily by dietary intake.[81] Beneficial effects of dietary AA and DHA intake on visual and cognitive development[17] of preterm and, to a lesser degree, term infants have been demonstrated and LCPUFAs are now routinely supplemented to preterm and most term infant formulas.[81]

The trans-fatty acid content of human milk also is influenced by material diet.[83,84] The main source of trans fatty acids in the diet is partially hydrogenated fats; trans fatty acids can comprise up to 60% of the fatty acids in shortenings and food sources made with shortenings. Trans fatty acids represented approximately 7.7% of the fatty acid intake (2.5% of energy) of lactating women and the primary dietary sources were bakery products and breads (32%), snacks (15%), fast foods (11%), and margarines and shortenings (11%).[85] Human milk trans fatty acid content varies worldwide, ranging from 0.2% to 0.8% in milk samples from China and Africa to 7% in milk of North American mothers.[85,86] High concentrations of trans fatty acids in human milk are of potential concern as they may adversely affect the growth and development of infants by interfering with *n*-3 and *n*-6 fatty acid metabolism or by altering membrane fatty acid composition.[83,85] Indeed, milk trans fatty acids are inversely associated with milk linoleic and α-linolenic acids.[83,85] Furthermore, trans fatty acid, linoleic acid, α-linolenic acid, AA, and DHA concentrations in milk were directly related to their concentrations in the plasma of breast-fed infants.[85] The inclusion of trans fatty acid content on food labels was associated with a decline in milk trans fatty acid content in Canadian mothers and a reduction in exposure of infants from 2.0 mg/kg/d in 1998 to 1.3 mg/kg/d in 2005, suggesting that increased consumer awareness of food sources of trans fatty acids has reduced their intake and subsequent secretion into milk.[85]

Dairy products and the meat of ruminant animals also are sources of trans fatty acids produced by bio hydrogenation of fatty acids in the rumen.[84,86] Dairy products typically contain 2%–5% trans fatty acids, primarily as conjugated isomers of linoleic acid.[86] Conjugated linoleic acids (CLAs) constitute a group of structurally related fatty acids with 18 carbons and two conjugated double bonds. The most abundant naturally occurring CLA in the human diet and human milk is rumenic acid ($18:2_{c9t11}$) (Table 29-2).[86] Rumenic acid is produced in the bovine and human mammary gland via the desaturation of vaccenic acid ($18:2_{t11}$) by

delta 9-desaturase (Δ9-desaturase).[86] Other forms of CLAs, such as $18:2_{t10c12}$, are found in dietary supplements and in low levels in human milk (Table 26-2).[86] Moreover, milk fat content was reduced by 25% in lactating women after consuming a CLA supplement for five days.[87] Thus, nursing mothers should be cautioned against consuming CLA supplements.[87]

Sterols

Milk sterols are composed of 90% cholesterol and 8.6% desmosterol with negligible quantities of phytosterols.[47,76] The cholesterol content of human milk declines from approximately 300–350 mg/L in colostrum to 100–200 mg/L in mature milk and concentrations are correlated with milk fat content.[47,76] Approximately 10%–15% of the cholesterol is present as cholesteryl esters, which, similarly, decline from 50 to 10 mg/L from colostrum to mature human milk.[88] Interestingly, unsaturated fatty acids are preferentially esterified to cholesterol (73 wt% of the fatty acids in cholesteryl esters).[88] Linoleic acid represented 31% of the fatty acids esterified to cholesterol versus 13% of the total fatty acids in milk.[88] Breast-fed infants consume approximately fourfold more cholesterol per day than adults (4.3 vs. 25 mg/kg body weight) and have higher circulating cholesterol concentrations than infants fed formula devoid of cholesterol.[81]

Phospholipids and Sphingolipids

Phospholipids are dipolar lipids that are present as a component of the MFGM. Their concentration in milk is approximately 250 mg/L or 0.6 g/100 g lipid.[47,76] The principal classes of phospholipids are sphingomyelin, phosphatidylcholine, phosphatidyl-ethanolamine, phosphatidylserine, and phosphatidylinositol.[47,76] Choline, which can be endogenously synthesized from phosphatidylcholine and sphingomyelin, is a major constituent of cell membranes in neural tissues and is essential for the formation of acetylcholine.[89,90] Recent studies have established a key role for prenatal and early postnatal choline intake for optimal hippocampal development and memory.[90] Human infants excrete in urine large amounts of betaine, a product of choline oxidation, regardless of choline intake, suggesting an obligatory choline requirement.[89] Infant formulas contain choline; however, the concentration may not be sufficient to meet the increased demand of the human infant.[89] In contrast, human milk choline concentration doubles between colostrum and mature milk

and appears to be sufficient to account for betaine excretion in full-term infants.[89] In addition, human milk contains several classes of sphingomyelin (100–200 μM), neutral glycosylceramides (1–20 mg/L), and acidic glycolipids (1–20 mg/L), including gangliosides.[47,76] Gangliosides may play a role in host defense by binding cholera and other toxins,[91] and in neural development.[92] Analysis of neural tissue collected postmortem from infants who had died of sudden infant death syndrome demonstrated greater ganglioside and glycoprotein SA content in the brain frontal cortex of breast-fed than formula-fed infants, suggesting increased synaptogenesis and differences in neurodevelopment.[92]

Protein and Nonprotein Nitrogen

Human milk nitrogen content declines from colostrum (3.0 g/L) to mature milk (1.9 g/L) (Table 29-1). The nitrogen component of human milk is composed of whey and casein proteins and over 200 nonprotein nitrogen (NPN) compounds.[47,93,94] Approximately 25% of the nitrogen in human milk is NPN; thus, human milk protein content is most accurately determined as (total nitrogen – NPN) × 6.25. Using this approach, the protein content of human colostrum and mature milk averages approximately 15–20 g/L and 9–10 g/L, respectively.[47,93,94] The protein content of mature human milk is markedly lower than cow's milk (35 g/L) and cow's milk- (13–15 g/L) or soy protein-based infant formulas (18–20 g/L).[93] Formulas not only contain more total protein than human but also contain a different pattern of amino acids.[93] Infants fed cow's milk-based formulas typically have higher urea N and amino acids, except taurine and cystine, than breast-fed infants.[93]

Protein

Human milk contains a heterogeneous mixture of proteins (casein and whey) and peptides. The protein content and composition of human milk undergoes dramatic changes during the course of lactation, which are matched to the developmental needs of the infant.[47,93,94] For example, colostrum is whey-predominant (90:10 whey to casein ratio) and contains higher concentrations of growth factors[94] and immune protective proteins, including sIgA, lactoferrin, and lysozyme, than mature milk.[94] As lactation progresses, the concentrations of growth factors and antimicrobial proteins decrease and casein increases, resulting in a whey to casein ratio of approximately 60:40 in mature human milk.[47,93,94] Milk produced by mothers delivering preterm is higher in total protein and some differences

in the casein and whey protein content compared to term human milk have been reported.[49,93]

Casein

There are four major families of casein proteins: α-casein, β-casein, γ-casein, and κ-casein.[47] Human milk is relatively low in casein (3–5 g/L) compared to bovine milk (26 g/L) and the forms of casein differ between the two species (Table 29-1).[93] The main caseins in human milk are β-casein (3–5 g/L) and κ-casein (1–3 g/L).[93,94] Alpha-casein, the predominant casein in bovine milk, is absent from human milk.[47,93] Casein proteins are high in proline and low in cystine and undergo extensive posttranslational phosphorylation and glycosylation.[93] Human milk κ-casein is more highly glycosylated (40% carbohydrate) than bovine κ-casein (10% carbohydrate).[93] Casein proteins precipitate at pH 4.6 and will form a "curd" in the infant's stomach. Human milk caseins tend to form looser micelles and softer curds, making them more easily digestible by carboxypeptidase. A number of peptides are formed during the proteolytic degradation of casein, which has been proposed to regulate intestinal motility (opioid-like compounds) or enhance calcium absorption (phosphopeptides).[95]

Whey

Whey is the fluid remaining following precipitation of casein micelles. In human milk, whey proteins account for 60%–70% of the total proteins versus 20% in bovine milk.[93] Human milk whey contains a variety of proteins, some of which are milk-specific and synthesized by the mammary gland (e.g., α-LA) and others of which are extracted from the maternal circulation (e.g., serum albumin) (Table 29-1). Alpha-lactalbumin is the predominant whey protein in human milk (28% of total human milk protein and 40% of whey protein), where as β-lactoglobulin is the primary whey protein in bovine milk and infant formulas and is absent from human milk.[94,96] A number of beneficial physiologic functions for both the mother and the infant have been ascribed to α-LA.[94,96] Within the mammary gland, α-LA participates in lactose synthesis and, as the major osmol in milk, lactose facilitates milk production and secretion.[96] For the infant, α-LA provides a well-balanced supply of essential amino acids and may enhance mineral and trace element absorption.[94,96] During α-LA digestion, peptides that have immunostimulatory and antibacterial

properties appear to be transiently formed.[96] Furthermore, a novel folding variant of multimeric α-LA, termed HAMLET (human α-LA made lethal to tumor cells), has been discovered that specifically enhances apoptosis of tumor, but not normal, cells.[96] The formation of HAMLET requires partial unfolding of the protein and its antitumor activity requires binding of oleic acid (C18:1) to the protein as a cofactor.[96] HAMLET has been proposed potentially to impact intestinal mucosal cell turnover, however, there is no evidence to date that it is formed in the gastrointestinal tract of human infants.[96] Although α-LA only composes 2%–3% of the protein in bovine milk, bovine α-LA-enriched whey sources are commercially available and currently are being used to produce infant formulas with higher α-LA content that have high protein quality.[96]

Functional Roles of Milk Proteins

In addition to serving as a source of amino acids, broader physiologic and immunologic roles of human milk proteins have been identified that provide nutritional and developmental benefits to the neonate.[96] For example, human milk proteins bind essential nutrients present in milk, which may enhance their bioavailability either through improved solubility or via direct interaction with receptors lining the gastrointestinal tract. Examples include haptocorrin for vitamin B_{12} and folate-binding protein, and the binding of minerals and trace elements to β-casein, α-LA, lactoferrin, and β-glycomacropeptide.[96]

As previously discussed, another key function of human milk proteins involves host defense, which occurs through antimicrobial protection, stimulation of immuno competence, and promotion of the establishment of a beneficial microbiota.[7] Roles for sIgA, lactoferrin, lactoperoxidase, and lysozyme in neonatal host defense have long been appreciated.[94] In addition, other milk proteins have been added to the cadre of immuno protective components, including haptocorrin[97] and κ-casein.[98] Another example of a multifunctional milk protein with a key role in the development and maintenance of the immune system is osteopontin (OPN).[99] OPN has been shown to regulate Th1-mediated immunity and to enhance host resistance to infections.[99] In addition, proteolytic products of milk proteins have been shown to exert bioactivities distinct from the intact proteins, contributing to the complexity of the potential interactions between milk components and the infant. For example, antimicrobial peptides were produced following an in vitro digestion of lactoferrin[100] and α-LA,[101] and bifidogenic peptides were produced from lactoferrin and

secretory component.[102] The multifunctional roles of proteins such as α-LA and lactoferrin and the potential for their proteolytic products to exert bioactive functions within the neonatal gastrointestinal tract illustrate the complexity of human milk protein bioactivity.[96]

Hormones and Growth Factors

Hormones and growth factors constitute another class of bioactive proteins and peptides in milk.[103] Many hormones have been reported in human milk, including parathyroid hormone,[104] insulin,[105] leptin,[106] ghrelin,[107] apelin,[107] nesfatin-1,[107] obestatin,[106,108] and adiponectin,[105,109,110] among others. The function of these hormones in milk and in the infant is still incompletely understood, but it is hypothesized that they are involved in the regulation of growth of various tissues and may be associated with the neonate metabolism and overall growth[110,111] On the other hand, growth factors such as insulin-like growth factor-I (IGF-I), epidermal growth factor, transforming growth factor-α and factor-β are among the most well studied.[103,112] Cell culture and animal models show that these growth factors can initiate cellular growth and expression of differentiated function and that they may be important in repair following intestinal injury.[103,112] There is evidence that orally administered recombinant growth factors survive digestion and exert biological effects within the neonatal gastrointestinal tract.[113] However, most of the published research investigating growth factors has applied supra physiological doses and there is little clinical data to support a direct role of any growth factor at the concentrations normally present in human milk on neonatal intestinal development.

Recent studies have identified neurotrophic growth factors in human milk, such as brain-derived neurotrophic factor (BNDF), glial cell-line-derived neurotrophic factor (GNDF), ciliary neurotrophic factor, and S100B protein.[114,115] Neurotrophic factors have been proposed to be important for the development of the postnatal enteric nervous system, peristalsis, and synaptic communication,[116] in addition to promote learning and memory processing.[117] BNDF and GNDF content in milk tends to decrease as lactation progresses,[114] where as S100B concentration in mature milk is higher than colostrum.[115]

Enzymes

A variety of enzymes are present in human milk that influence the

digestion of other milk components including plasmin, prothrombin, cathepsins, and kallikrein.[118] Plasmin and cathepsin are responsible for the cleavage of milk OPN into biologically active fragments that have a role in cell adhesion.[119] BSSL improves the digestion and absorption of lipids and lipid-soluble vitamins,[120] where as protease inhibitors, such as α_1-antitrypsin and antichymotrypsin, limit the digestion of some milk proteins.[121] This latter function may be critical to preserving the physiologic functions of the nutrient-binding and immunologic proteins within the neonatal gastrointestinal tract. Indeed, intact human proteins are present in the feces of both term and preterm infants.[56]

NPN

Approximately 20%–25% of the nitrogen in human milk is present as NPN, which is considerably higher than the proportion of total N present at NPN in bovine milk (5%).[47,93,122] The NPN content of infant formulas is variable and is influenced by whether the whey protein concentrate was prepared by electro dialysis or ultra filtration, the latter of which removes more NPN components.[122] The NPN components are less than 10,000 mol wt nitrogen-containing compounds. The NPN in human milk comprises a heterogeneous group of more than 200 compounds including urea, free amino acids, such as taurine and glutamine, small peptides, including many growth factors, amino sugars, nucleic acids, polyamines, nucleotides, and carnitine.[47] A number of these compounds have physiological roles in the infant and their concentrations are lower in the plasma of formula-fed versus breast-fed infants. This observation led to the addition to infant formulas of taurine and carnitine in the 1980s and, most recently, nucleotides. Urea N accounts for approximately 50% of the NPN in human milk[122] and appears to be utilized to synthesize nonessential amino acids. Heine and colleagues[123] estimated that 2%–3.6% of serum proteins are synthesized from urea N, and 10%–40% of the ^{15}N from an oral dose of ^{15}N, ^{15}N-urea was retained by preterm infants.[122] Thus, while NPN is not included in the protein fraction of human milk, it may contribute to the pool of available nitrogen for protein synthesis by the infant.

Vitamins

Human milk contains all the essential water-soluble and fat-soluble vitamins and their content can be influenced by maternal status diet.[124–127]

Healthy breast-fed infants of well-nourished mothers are at low risk for vitamin deficiencies and the need for vitamin supplementation is rare, with a few exceptions where milk concentrations may be inadequate. Examples include vitamin B_{12} in milk of vegan mothers, vitamin D in milk produced by mothers with insufficient dietary intake or sun exposure, and vitamin K in most mothers.[128] Vitamin D and K deficiencies have been described in breast-fed infants and these are the only two vitamins for which supplementation for the breast-fed infant is recommended by the AAP.[129,130] These will be discussed in greater detail below.

Fat-Soluble Vitamins

Most fat-soluble vitamins are delivered to the infant within the MFGM and their absorption is enhanced by BSSL in milk.[120] An exception is vitamin D, which is found in the whey bound to vitamin D-binding proteins.

Retinoids and Carotenoids

Retinoids and carotenoids comprise a group of closely related compounds that have vitamin A activity (e.g., retinol), can be converted to vitamin A (e.g., β-carotene, α-carotene, β-cryptoxanthin), or do not have provitamin A activity, but have other physiological functions in the body (e.g., lutein, zeaxanthin, lycopene).[131,132] For example, lutein and zeaxanthin are the only dietary carotenoids present in macular pigment and may protect photoreceptors against light-initiated oxidative damage.[131] Colostrum and breast milk are rich in retinoids, principally as retinol esters (Table 29-3).[130–134] Retinol ester is the principal form of vitamin A in human milk. Its concentration is influenced by maternal diet and varied approximately twofold across eight countries.[134] Retinol concentration in term human milk declined as lactation progressed; however, this trend was not observed in preterm human milk and the absolute concentrations were higher in transitional and mature preterm than term milk.[133] Human milk contains approximately 1.8 μmol/L total carotenoids, with the provitamin A carotenoids (α-carotene, β-carotene, β-cryptoxanthine) accounting for 50% of the carotenoids.[132] In general, the carotenoid content declines from colostrum to mature milk, but the magnitude of decrease was influenced by the polarity of the carotenoids, with the most polar carotenoids exhibiting the smallest decrease.[134] Thus, colostrum had a higher proportion of less polar carotenoids (e.g. β-carotene), where as mature milk contained more lutein and zeaxanthin.[133] Lietz and colleagues[131] demonstrated that human milk α- and β-carotene content could be

increased by dietary supplementation, without decreasing milk lutein or zeaxanthin content. They also showed that the concentrations of hydrocarbon carotenoids (α- and β-carotene) were greater in maternal plasma than milk, where as the opposite was true for xanthophylls (lutein or zeaxanthin), suggesting regulated uptake and transport of polar carotenoids into milk.[131]

Vitamin D

Unlike the other fat-soluble vitamins, vitamin D is present in whey-attached vitamin D-binding proteins.[47] The principal form of vitamin D is 25-OH vitamin D and its content is influenced by maternal diet and sun exposure.[47,130,135] Endogenous vitamin D synthesis is detrimentally impacted by darker skin pigmentation and other factors that reduce skin UVB exposure, including the winter season, environmental pollution, use of sunscreens, and lifestyle or cultural practices that limit sunlight exposure.[136] Greer and colleagues showed that milk vitamin D content could be increased 10-fold by 1.5 MED (minimal erythemal dose of total body UVB exposure), which is approximately 90 seconds of irradiation in Caucasians.[137]

Exclusively breast-fed infants can obtain vitamin D from human milk, by endogenous synthesis from sunlight exposure or by mobilizing vitamin D stored during gestation. However, vitamin D stores of infants are rapidly depleted, even in infants born to mothers with normal vitamin D status and after 2 months of age, infants are dependent upon exogenous sources of vitamin D.[130] Human milk typically contains 1 μg or 40 IU/L or less of vitamin D (Table 29-3), which is insufficient to meet the current vitamin D recommendation for infants of 400 IU/d.[130] Furthermore, the AAP recommends that infants less than 6 months of age be kept out of direct sunlight and that protective clothing, as well as sunscreen, should be used for infants 6 months and older.[130] To reduce the risk of rickets, the AAP currently recommends a daily supplement of 400 IU for all breast-fed infants and for non breast-fed infants receiving less than 1000 mL/d of vitamin D-supplemented formula for the first two months of life.[130]

TABLE 29-3 Vitamin Composition of Human Milk

Constituent (per L)	Colostrum	Mature Milk
Fat-soluble vitamins		
Vitamin A and carotenoids		

Retinol esters (μmol)	1.45–2.0	1.22
Total Carotenoids (μmol)	5.35	1.8–3.0
α-Carotene (μmol)	0.17	0.02–0.03
β-Carotene (μmol)	0.42	0.04–0.07
β-Cryptoxanthin (μmol)	0.23	0.03–0.06
Lutein/Zeaxanthin (μmol)	0.2	0.04–0.10

Mean values adapted from References.[47,128,132,133,145,152,153,177]

Vitamin E and Coenzyme Q10

Analogous to vitamin A, the term “vitamin E” describes a family of closely related compounds (α, β- and γ-tocopherol) that function as antioxidants in cell membranes by scavenging free radicals. Human milk contains α- and γ-tocopherol, but insignificant levels of β-tocopherol.[134] The α- and γ-tocopherol content of colostrum is greater than of mature milk (Table 29-3).[134] In addition, the α- and γ-tocopherol content of preterm human milk is greater than milk from mothers delivering at term.[134] Infants appear to differentially utilize natural and synthetic forms of vitamin E,[138] but both human milk and formula contain sufficient vitamin E to meet requirements.

Recently, coenzyme Q10, a lipophilic antioxidant, has been reported in

term and preterm human milk[139,140] and the coenzyme Q10, α- and γ-tocopherol concentrations were directly correlated with the antioxidant capacity of the milk.[140] Compared to term human milk, the coenzyme Q10 content was lower in colostrum (0.50 vs. 0.81 μmol/L) and transitional (0.45 vs. 0.75 μmol/L) milk from mothers delivering preterm.[140] In term human milk, coenzyme Q10 content declined from colostrum (0.80 μmol/L) to transitional (0.57 μmol/L) and mature milk (0.44 μmol/L) samples, which was more evident when expressed on the basis of milk cholesterol content, 137, 86, and 67 μmol/mol, respectively.[139]

Vitamin K

Vitamin K (phylloquinone) is a necessary cofactor for the vitamin K-dependent carboxylase, which catalyzes the formation of γ-carboxyglutamic acid (Gla). The formation of Gla residues creates calcium-binding sites that are necessary for the function of coagulation factors (II, VII, IX, and X), protein C, protein S, protein Z, osteocalcin, Prolin rich Gla proteins (one and two), and Conantokin (G and T).[141] Vitamin K is not readily transported across the placenta; thus, vitamin K deficiency can cause unexpected bleeding in the first week of life.[129] The AAP currently recommends that a single, intramuscular dose of vitamin K (0.5–1.0 mg) be given to all newborns to prevent vitamin K deficiency bleeding.[129] In addition, it has been suggested that exclusively breast-fed infants receive oral supplementation of 1 mg of Vitamin K weekly until 12 weeks postpartum.[141]

Human milk contains both forms of vitamin K, phylloquinone (K_1) and menaquinones (K_2),[142,143] with milk menaquinone-4 (MK-4) being synthesized in the body from dietary phylloquinone.[144] Overall, a weak relationship has been noted between maternal dietary phylloquinone intake and milk phylloquinone content, however, the vitamin K content and composition can be impacted by maternal diet and supplement use.[126,142,144] Maternal supplementation with a pharmacological dose of 5 mg phylloquinone per day increased its concentration in milk and in the serum of breastfeeding infants.[126] Another form of menaquinome (MK-7) has been detected in breast milk of Japanese women.[145] MK-7 is synthesized by bacteria and is associated with the intake of a regional fermented soybean product. Prophylactic vitamin K administration is particularly important for exclusively breast-fed infants because human milk vitamin K (phylloquinone) concentrations (typically 1–3 μg/L) (Table

29-3) are insufficient to meet the recommended intake for infants of 2 µg/d.[129] In addition, *bifidobacteria*, which are more predominant in breast- than formula-fed infants, do not synthesize vitamin K and the vitamin K content in the stool of breast-fed infants was insignificant compared to formula-fed infants.[146]

Water-Soluble Vitamins

The concentrations of water-soluble vitamins in human milk are influenced by maternal nutritional intake and vitamin supplementation.[127,147] The thiamin and riboflavin contents of human milk typically are sufficient to meet the needs of the exclusively breast-fed infant, but vitamin B_6, vitamin B_{12}, and folate may be low in milk produced by mothers from lower socioeconomic groups.[127] Although supplementation may be beneficial for women with poor dietary intake, only niacin and vitamin B_{12} can be increased further in milk when the mother's vitamin status is adequate.[47,147]

Vitamin C

The concentration of ascorbic acid in human milk can range from 40 to 100 mg/L in well-nourished women and within an individual mother the concentration decreases from colostrum to mature milk[47] (Table 29-3). Low maternal intake reduces milk ascorbic acid content. For example, mean human milk ascorbic acid was 50% lower in the milk of African (31 mg/L) versus European (63 mg/L) women.[148] Furthermore, ascorbic acid supplementation (1000 mg/d for 10 days) modestly increased milk ascorbic acid content in European women (60–70 mg/L) versus (19–60 mg/L) in African women.[148] In African women, one serving of orange juice per week had no significant effect, where as three or five servings/week (100 mg ascorbic acid/serving) for six weeks doubled mean human milk ascorbic acid content from 16 to 32 mg/L.[148] Human milk ascorbic acid is sufficient to meet the needs of exclusively breast-fed infants and no supplementation is recommended.[128]

Thiamine

Thiamine is present in both free (30%) and phosphorylated (70%) forms in human milk.[124] The thiamine content of colostrum is low (20 µg/L), but increases to 160–200 µg/L in mature milk and this amount can be further increased with maternal supplementation (Table 29-3). The thiamine

intake of breast-fed infants is lower than the recommended dietary allowance (RDA), however, the intake appears adequate to meet their needs and infantile beriberi is rare in the United States[128] Other than ensuring adequate maternal thiamine intake, supplementation of the infant is not recommended.[128]

Riboflavin

Riboflavin is present in human milk as both riboflavin and flavin adenine dinucleotide.[124] The riboflavin content of colostrum is high and decreases to 400–600 µg/L in mature human milk (Table 29-3). Riboflavin deficiency in women is associated with low concentration of riboflavin in milk.[124] However, in well-nourished women, riboflavin is only increased by pharmacological intakes (>3 times the RDA).[47] The riboflavin intake of breast-fed infants is adequate and no supplementation of infants is needed.[128]

Niacin

The niacin content of colostrum is approximately 0.5 mg/L and 1.5–2.0 mg/L in mature milk (Table 29-3). The content in milk can be increased to as high as 6.0 mg/L by maternal intake.[47,147] In addition, niacin can be synthesized from excess dietary tryptophan, which contributes to the milk niacin content.[47,147] Niacin supplementation is not recommended for exclusively breast-fed infants.[128]

Vitamin B_6

The vitamin B_6 (pyridoxal, pyridoxal phosphate, pyrodoxamine, and pyridoxine) content of colostrum is low and increases to 90–310 µg/L in mature milk (Table 29-3).[47,127] Vitamin B_6 in human milk of well-nourished women is adequate for the exclusively breast-fed infant[128]; however, low maternal intake can reduce milk B_6 content.[127,149]

Folate and Vitamin B_{12}

The folate (5-methyltetrahydrofolate) content of human milk increases from 5 to 10 µg/L in colostrum to 50–100 µg/L in mature milk[127] and its concentrations remain constant with maternal deficiency or supplementation.[124] It was estimated that one-third of pregnant and lactating women are not meeting their folate requirement by diet alone,

even after the mandatory supplementation of folate to enriched flour, pasta, and grains in North America in 1998.[150] However, folate deficiency has not been reported in breast-fed infants and supplements are not recommended for the infant.[128]

The content of vitamin B_{12} in human milk decreases from colostrum (approximately 1.2 μg/L) to mature milk (approximately 0.5 μg/L).[128,147] Infants of well-nourished mothers with adequate vitamin B_{12} intake do not require supplementation. However, the vitamin B_{12} content of milk of vegan mothers can be insufficient to meet the needs of the exclusively breast-fed infant and deficiencies have been reported.[151] Thus, in some clinical situations, supplements of vitamin B_{12} are warranted for the mother or infant.[128]

Biotin and Pantothenic Acid

The biotin content of colostrum is approximately 4.5 μg/L and its concentration increases to 5–9 μg/L in mature milk (Table 29-3).[152] However, mature milk biotin does not reach a stable plateau and varies substantially between mothers (0–27 μg/L)[152] (Table 29-3). The concentration of pantothenic acid in human milk is 2.0– 2.5 mg/L[153] (Table 29-3). There were no differences in milk pantothenic acid concentrations between two weeks and four months postpartum, but its concentration was responsive to maternal dietary intake.[153] Pantothenic acid was also higher in preterm (3.5 mg/L) versus term (2.5 mg/L) human milk.[153]

In summary, in well-nourished women, human milk contains all essential vitamins at adequate concentrations to meet the needs of the exclusively breast-fed infant. Two exceptions are vitamins D and K, but deficiencies can be avoided by adequate maternal dietary and maternal sun exposure, in the case of vitamin D, and prophylactic vitamin K injection at birth. Mothers following restricted diets or those with previous gastric bypass surgery are at risk for low milk vitamin B_{12} content and should be encouraged to take supplemental vitamin B_{12}. As the content of all fat- and water-soluble vitamins in human milk are influenced by maternal intake, it may be prudent to encourage all lactating mothers to consider a daily multivitamin supplement to ensure adequate milk nutrition content.[124]

Macro- and Microminerals

Over 20 macro- and microminerals have been identified in human milk and, in general, their content changes over the course of lactation, with most declining from colostrum to mature milk.[154–156] In direct contrast to vitamins, mineral concentrations in milk generally do not correlate to maternal serum or typical dietary intake[157] and do not respond to supplementation.[158] Mineral transport into milk is tightly regulated by the mammary gland.[159] Specific micromineral (Cu, Zn, and Fe) transporters have been identified and their molecular and hormonal regulation is under study.[159] The absolute concentrations of most macro- and microminerals are lower in human milk than bovine milk or infant formulas;[155,156] however, they are characterized by enhanced bioavailability.[160] Thus, the mineral requirements of exclusively breast-fed term infants can be met for the first six months of life.[47,160]

Macrominerals

The major macrominerals in milk include calcium, magnesium, phosphorus, sodium, potassium, and chloride[47,94,155] (Table 29-4). Electrolytes, such as sodium and potassium, are totally soluble in water and found primarily in whey. In contrast, calcium forms complexes with phosphate and casein; 85% is found in the whey and 15% associated with casein micelles in calcium–phosphate linkages.[161]

TABLE 29-4 Macromineral and Micromineral Composition of Human Milk

Constituent (per L)	Colostrum	Mature Milk
Macrominerals		
Calcium (mg)	250	200–250
Chloride (mg)	600–800	400–450
Magnesium (mg)	30–35	30–35
Phosphorus (mg)	120–160	120–140
Potassium (mg)	600–700	400–550
Sodium (mg)	300–400	150–250
Microminerals		
Boron (μg)	30	28
Chromium (μg)	17	25–75
Copper (mg)	0.5–0.8	0.1–0.3

Fluoride (μg)	5–20	4–15
Iodine (μg)	40–50	140–150
Iron (mg)	0.5–1.0	0.3–0.75
Manganese (μg)	5–12	3–4
Selenium (μg)	25–32	10–25
Zinc (mg)	5–12	1–3

Mean values adapted from References.[47,154–156,161,162,165,166]

Calcium, Magnesium, and Phosphorus

Calcium content of colostrum (300–350 mg/L) is greater than human mature milk (200–250 mg/L)[154,155] (Table 29-4), but both are markedly lower than that present in bovine milk (1200–1350 mg/L).[154] Once lactation is established, the calcium and magnesium content of human milk is relatively stable between (3–26 weeks postpartum), where as human milk phosphorus content declines approximately 40% during that time frame.[162] Calcium bioavailability is high from human milk, due in part to the calcium to phosphorus ratio of 2:1, and the levels of calcium, phosphorus, and magnesium in human milk are adequate to meet the needs of the term human infant.[47] For preterm infants, preterm or donor human milk should be fortified with a human milk fortifier to prevent rickets and hyocalcemic tetany.[163]

Sodium, Potassium, and Chloride

The concentrations of electrolytes in milk are influenced by an electrochemical gradient in the mammary secretory cells, which is established by the passage of water.[47] In early lactation, changes in the concentrations of lactose, sodium, and chloride signal closure of paracellular pathways between the mammary epithelial cells at one to two days postpartum.[37] Overall, the concentrations of sodium, potassium, and chloride are lower in mature milk than colostrum, but the magnitude of difference is greater for potassium and chloride (60%–70% lower) than sodium (30%–35% lower).

Microminerals

The predominant trace elements in human milk include iron, copper, and zinc, as well as, manganese, selenium, chromium, fluoride, iodine, and boron[47,154,155] (Table 29-4). The concentrations of trace elements in human milk are low; however, their bioavailability is much higher than from bovine milk or infant formula.[160] The presence of lactoferrin in

human milk has been proposed to facilitate iron and manganese uptake via an intestinal receptor for this protein.[160] Furthermore, high concentrations of ascorbic acid and citrate also may facilitate the uptake of trace elements from human milk, where as a high concentration of casein in cow's milk and cow's milk formulas may limit trace element absorption from these diets.[160] The physical distribution of trace elements differs between human and cow milk, which also may influence their bioavailability.[161] For example, in bovine milk 24% of the iron, 44% of the copper, and 84% of the zinc are bound to casein, where as comparable values for human milk are 9%, 7%, and 8%, respectively, and most of these trace elements are found in the human milk whey.[160] A significant proportion of the iron in both bovine (14%) and human (33%) milk is associated with the outer MFGM.[161]

Iron, Zinc, Copper, and Manganese

The iron concentration in human milk averages 0.5–1.0 mg/L in colostrum and 0.35–0.70 mg/L in mature milk[154,162] (Table 29-4). The bioavailability of iron from human milk is high (20%–50%) relative to infant formulas (4%–7%).[160] Exclusively breast-fed infants generally do not need iron supplements prior to 6 months of age, at which time the AAP recommends the gradual introduction of iron-enriched solid foods, such as iron supplemented rice cereal.[164] Infants who have low iron stores may require iron supplementation prior to 6 months of age to avoid iron-deficiency anemia.[164] However, trace elements that share absorptive pathways compete for uptake, and excessive iron supplementation may create imbalances in the ratios between trace elements (Fe/Zn, Zn/Cu, Fe/Mn) and impair trace element absorption.[160] The zinc concentration of human milk rapidly declines from 5 to 12 mg/L in colostrum to 1–3 mg/L in mature milk,[154,162] and does not seem to be influenced by maternal dietary intake.[156] Similarly to iron, the bioavailability of zinc from human milk (60%) is greater than from formula (approximately 30%).[160] Following a similar trend to iron and zinc, the copper content of human colostrum and milk declines from colostrum (0.5–0.8 mg/L) to mature milk (0.1–0.3 mg/L), although the extent of the decline is less than those observed with iron and zinc.[156,165] Copper absorption is similar from human milk (25%) and cow's milk-based infant formula (23%); however, the copper concentrations in formula are double that of human milk, suggesting the potential for excess copper intake in formula-fed infants.[165] Similar to the

other trace elements, the manganese content of human milk (3–4 μg/L) is lower than colostrum (5–12 μg/L)[154,162] and its bioavailability from human milk is greater than from infant formula.[160]

Selenium, Iodine, and Fluoride

The selenium, fluoride, and iodine concentrations inhuman milk vary worldwide. Mean selenium concentrations in colostrum and milk are 33–40 and 8–12 μg/L, respectively[154,162] (Table 29-4). Maternal selenium status has a strong influence on milk selenium content and a multi country comparison showed that levels in milk from the Philippines was much higher than milk from Swedish or Hungarian mothers.[154] Likewise, milk fluoride was reported to vary from 7 to 118 μg/L in samples collected worldwide, but does not appear to be affected by stage of lactation.[154] In many countries, fluoride is supplemented to the water supply. Esala and colleagues[166] compared milk samples collected from mothers living in two areas having an average of 0.2 and 1.7 mg fluoride/L in the drinking water. The fluoride content of breast milk in the high-fluoride areas (10.9 μg/L; range 4.5–50.7 μg/L) was significantly higher than the low-fluoride areas (7.0 μg/L; range 4.3–14.0 μg/L), respectively.[166] To avoid fluorosis, the AAP recommends that fluoride not be directly administered to infants during the first six months after birth, whether they are breast- or formula-fed.[1] During the period from 6 months to 3 years of age, breast-fed (and formula-fed) infants require fluoride supplementation, only if the water supply is severely deficient in fluoride (<0.3 mg/L).[1] Lastly, milk iodine content varies widely by geographic location and maternal intake and iodized salt and seafood are primary dietary sources.[167] A recent systematic review of human milk iodine content showed a range of 12–155 μg/L, with the lowest concentration found in areas with high prevalence of goiter.[167] In Germany, the mean iodine content of human milk increased sixfold from 1982 to 1996 due to maternal iodine supplementation.[167]

In summary, milk mineral content, with the exception of selenium, iodine, and fluoride, is not significantly influenced by maternal diet. In well-nourished women, human milk contains all essential macro- and microminerals at adequate concentrations to meet the needs of the exclusively breast-fed infant for the first 6 months of life and supplements are not recommended under normal circumstances.

DRUGS, ENVIRONMENTAL CONTAMINANTS,

AND VIRUSES IN HUMAN MILK

The presence in breast milk of environmental chemicals that may disrupt the nervous, endocrine, and reproductive systems of humans has gained increased attention from regulatory agencies and women's and children's health advocates.[168–171] Environmental chemicals in milk encompass substances that are introduced from food, pharmaceuticals, or exposure to environmental contaminants.[168–171] Although scientific evidence to date indicates that the advantages of breastfeeding outweigh any risks from contaminants, it is important to identify contaminant trends, locate disproportionately exposed populations, and take public health measures to decrease and eliminate chemical pollutants from mother's milk.[169] This is particularly important, as human milk often serves as the sole source of nutrition for the breast-fed infant and owing to the rapid mental and physical development that occurs in the early postnatal period, infants can be more susceptible to adverse effects resulting from chemical exposures than adults.[169,170]

Pharmaceuticals and Drugs

Drugs may enter into milk through medical treatment or recreational drug use.[168,171] Factors affecting the transfer of compounds into milk include their ionization (pKa of the compound), lipid solubility, maternal plasma protein binding, and molecular weight.[168] In general, small (<200 Da), ionized, lipid-soluble compounds will appear in milk within one hour after maternal ingestion and the plasma to milk ratio of the drug will be close to one.[168] For most drugs, the percentage of the maternal dose that is transferred to milk is between 0.5% and 1.0%, but there are some striking exceptions including certain beta blockers, where more than 5% of the maternal dose has been identified as passing into milk.[168] There have been very small numbers of reports of adverse reactions in the infant as a result of maternal drug ingestion.[169] Although the use of antidepressant medication during lactation is controversial, Davanzo[172] concluded after a recent review of the literature that selective serotonin reuptake inhibitors and nortriptyline were safe during lactation, but tricyclic doxepin and nefazodone should be avoided. Specific recommendations for the clinical management of breastfeeding mothers when medical treatment is necessary, including the use of radioisotopes, can be found in the AAP statement[171] and in the LactMed database, under the Toxicology data network of the U.S. National Library of Medicine

(http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT).

Environmental Contaminants

Decades of inadequately controlled pollution of the environment by "persistent, bioaccumulative and toxic" (PBT) chemicals has resulted in the contamination of human milk by polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane and its metabolites, dioxins, dibenzofurans, polybrominated diphenyl ethers, and heavy metals.[168] Women may be exposed to lipophilic chemicals through air, food, water, and occupational and household environments. These compounds are encountered to differing extents among women in industrially developed versus developing countries.[168] Some of the highest levels of milk contaminants are seen in developing countries among women living in agricultural areas, which are extensively treated with pesticides, and in the Canadian Inuit, who eat species high on the marine food chain that accumulate heavy burdens of PBT chemicals.[170]

Lipophilic chemicals are stored and accumulated over time in body fat and are mobilized during lactation. Generally, chemicals enter breast milk by passive transfer from plasma, and their concentration in milk is proportional to their solubility and lipophilicity. Twenty percent or more of maternal body burden of some persistent pollutants, such as PCBs, can be transferred during six months of lactation.[168] Although the levels of PBTs in human milk increase with the age of the mother,[169] the pattern of contaminant concentrations in milk over the course of lactation is still debatable. LaKind and colleagues reported that lipid-adjusted concentration of certain organic chemicals in milk and serum of lactating women did not decreased consistently over time. The study was conducted in samples collected from 10 women, thus additional studies with larger cohorts are needed to corroborate the findings.[173] However, studies of infants exposed to environmental chemicals in human milk have, for the most part, not shown adverse health effects for the nursing infant.[169] Thus, while more research is needed, current scientific evidence does not support altering the global public health recommendation of exclusive breastfeeding for six months followed by continued breastfeeding for the first year or beyond.[1,33,169,170]

Human Immunodeficiency Virus Type 1

Transmission of human immunodeficiency virus type 1 (HIV-1) through breastfeeding has been conclusively demonstrated.[174] Therefore, to avoid

mother-to-child transmission, the AAP and CDC recommend complete avoidance of breastfeeding by HIV-1-infected mothers in the United States.[175] However, in low- to mid-income countries, where infant morbidity and mortality rates are high, breastfeeding may outweigh the risk of HIV infection. Infants who received mixed feeding (breastfeeding and solid foods or formula) were at a higher risk of acquiring HIV infection.[176] For HIV endemic areas, the recommendation is for exclusive breastfeeding during the first months of life followed by extended antiretroviral therapy to the infant.[1,176]

OVERALL SUMMARY AND CONCLUSIONS

Breastfeeding is the optimal form of nutrition for the human infant and has numerous nutritional advantages over infant formula. In addition, human milk confers short- and long-term health protection against infection and autoimmune disease and may have lifelong consequences reducing chronic disease incidence. All mothers should be strongly encouraged by health care providers to breastfeed their infants, and medical, governmental, and societal programs should be established to support exclusive breastfeeding for the first six months of life, including ensuring that all hospitals become "Baby Friendly."[30]

30 Protective Properties of Human Milk and Bacterial Colonization of the Neonatal Gut

Anne Donnet-Hughes, PhD, Eduardo J. Schiffrin, MD, PhD, and W. Allan Walker, MD

Human breast milk is an undeniably unique, naturally adapted nutritional source for the human infant. It contains macronutrients, micronutrients and biologically active compounds.[1] However, in addition to the nutritive value it imparts, breast milk and breastfeeding are well recognized to protect against gastrointestinal infections, diarrheal diseases,[2] and respiratory infections.[3] Such protective effects have been variously ascribed to the presence in milk of maternal leukocytes,[4] immunoglobulins,[5] growth factors, oligosaccharides, and other immune factors.[6] While some of these components interact directly with bacteria, virus, and other pathogens, others mediate their effects by promoting proliferation, maturation, and activation of neonatal immune cells and by ensuring homeostasis. The net result is an enhanced protection of the immature intestine against colonization and invasion by pathogenic

bacteria.

An emerging concept is that breast milk can influence the neonatal immune system's perception of "danger" or "infectious non-self". To do so, some milk molecules[7] may actually facilitate the intestinal response to specific microbial motifs by activating intracellular signaling pathways such as that of nuclear factor (NF)-κB, a major regulator of the inflammatory response. At first, this might appear to contradict the recognized anti-inflammatory effect of breast milk. However, controlled innate activation is responsible for triggering homeostatic and defensive functions.[8]

The present chapter will elaborate further on how breast milk factors may modulate the neonate's perception of danger signals while avoiding exaggerated inflammation and tissue damage. It will address factors that promote a beneficial microbial flora either directly or indirectly via education of neonatal cells and challenge the theory that milk is strictly anti-inflammatory by proposing novel mechanisms by which the mother already educates her infant in the immediate postnatal period.

THE INNATE MUCOSAL IMMUNE RESPONSE IN THE MATURE INTESTINE

The intestine is the largest immune compartment in the body and, as such, the immunological events taking place in its tissues have a major impact on the overall immune status of the host. A prerequisite for a healthy intestine is an immune system that can detect harmful luminal antigens and pathogens and initiate a protective response, while remaining tolerant to innocuous microbes and dietary antigens as well as endogenous host cells and molecules.[9,10]

A single layer of epithelial cells forms an effective physical barrier that limits interaction between the contents of the intestinal lumen and the lamina propria and lymphoid follicles of the underlying tissue (Figure 30-1). Reinforcement of this barrier is provided by a thick layer of mucin (MUC) glycoproteins that are secreted by goblet cells and cover the epithelium surface. Together with other secretory molecules such as secretory IgA (sIgA) and antimicrobial peptides (AMP), the MUC sensure that the bulk of the gut microbiota is retained in the lumen.[11]

Virtually all human tissues and cells exposed to microbes are able to produce AMP. These molecules have broad-spectrum antibiotic activity against bacteria, viruses, yeast, and fungi and as such, they can shape the

composition of the commensal microbiota and confer protection against environmental and pathogenic organisms.[12] The gut AMP comprise multiple families, including defensins, cathelicidins, and C-type lectins that are secreted by epithelial cells and are retained within the mucus layer.[12] Only low concentrations reach the lumen. Moreover, there is a clear partitioning of the AMP within the mucus layer[8] with C-type lectin products such as RegIIIγ, being concentrated in the poorly colonized inner mucus layer, and defensins being retained in the outer layer.

Most AMP belong to the two structurally distinct classes of defensins and the C-type lectins.[13] α-Defensins are constitutively expressed in human neutrophils and Paneth cells of the small intestinal crypts and do not require bacterial signals for expression. β-defensins, produced predominantly in intestinal epithelial cells (IECs), can be both constitutive and inducible, while the inducible C-type lectin RegIIIγ is up-regulated in the small intestine and colon in response to bacteria.[13] Another third type of AMP, cathelicidin (LL-37/hCAP18), is expressed by neutrophils and mast cells, as well as by differentiated epithelial cells in the colon and stomach and in Brunner's glands of the duodenum.[13]

Paneth cells are considered particularly important in antibacterial defense as they secrete other AMP such as lysozyme and secretory phospholipase A2.[14] The functional significance of these cells and their expression of AMP have been demonstrated in animals which have increased bacterial translocation and susceptibility to infection[15] following ablation of the Paneth cell population.

The intestinal epithelium is not an inert barrier. It monitors changes in the lumen and discriminates the diverse luminal antigens. When needed, it collaborates with professional immune cells in the intraepithelial compartment and in the lamina propria, to mount rapid immune responses to protect the host against harm.[16] Any delay in response to real threat could seriously compromise the host thus, an alert is triggered by all microorganisms. However, the magnitude and precise nature of the response are determined by the characteristics of the microbe.

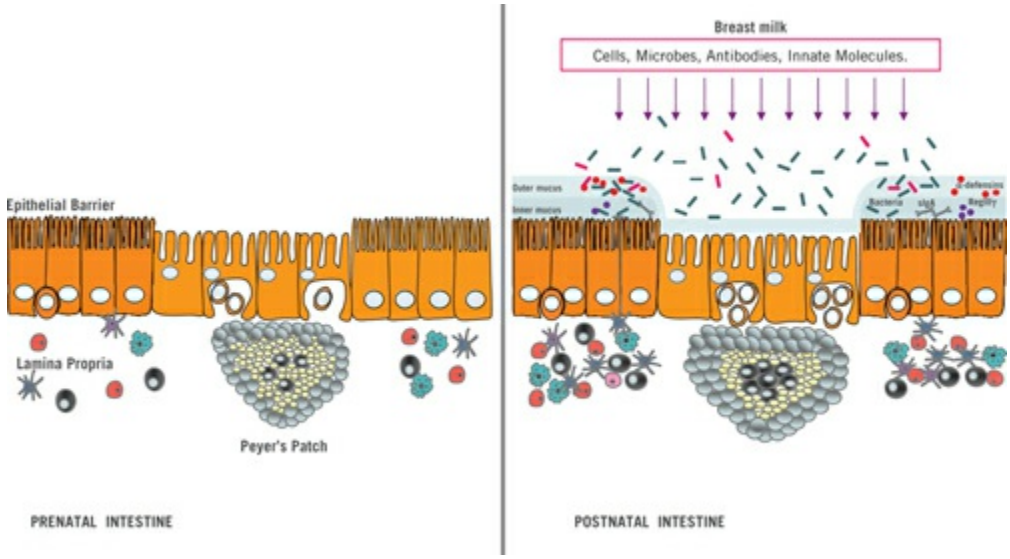

Figure 30-1 The prenatal intestine has all the main elements of the intestinal immune system including the epithelial barrier, immune cells in the lamina propria and organized lymphoid tissues such as Peyer's patches. In the postnatal period, breast milk compensates for deficits in endogenous immune factors and, together with colonizing bacteria, promotes functional maturation of this mucosal immune system. Maturational changes include increased production of mucus and antimicrobial peptides (e.g., defensins, RegIIIγ) into the lumen; increased number of lymphocytes in the intraepithelial compartment; larger and more numerous Peyer's patches with more developed germinal centers and increased numbers of immunoglobulin-producing cells; and increased cellularity in the lamina propria.

Broadly speaking, non-pathogens induce limited responses with a transient innate component[17] that might explain the low grade, physiological inflammation observed in the intestine. In contrast, pathogens induce rapid and more vigorous responses that are accompanied by some tissue damage. Thus, the host reaction can be considered as a stratified response whose primary tier is triggered by most bacteria and is pro-inflammatory, but whose second level of activation involves an assembly of gene products that are defined by the virulence traits of the organism.[18]

The initial innate response depends on the expression of pattern recognition receptors (PRRs) such as toll-like receptors (TLR), Nucleotide-binding oligomerization domain (NOD)-like receptors, and C-

type lectinreceptors.[19] These PRRs empower host cells to recognize and respond appropriately to a number of microbial components and endogenous host proteins.

The transmembrane TLR family of PRR molecules is perhaps the best-studied. Their expression can be constitutive or induced by different signals, and is dependent on the cell type and intestinal location.[19] TLR1, 2, 4, 5, and 6 are localized on the plasma membrane whereas TLR 3, 7, 8, and 9 are localized on the endosome membrane and interact with internalized ligands.[20] In enterocytes and colonocytes, TLR expression is polarized with low expression of TLR2 and 4 on the apical membrane and expression of TLR5 on the basolateral membrane. Activation of specific, spatially regulated TLR may provide a measure of microbial virulence[20] and permit some level of specificity in the primary immune response.

Upon ligand binding to TLRs, their cytoplasmic domain activates a cascade of adapter signaling molecules that include myeloid differentiation marker (MyD88), IL-1 receptor-activated kinase (IRAK), and tumor necrosis factor receptor-associated factor (TRAF)-6. Their sequential recruitment leads to activation of NF-κB and mitogen-activated protein kinases (MAPK) and induction of an inflammatory response.[21]

NOD1 and NOD2 are a structurally distinct family of intracellular, cytosolic PRRs that are expressed in IECs, Paneth cells,[22] in macrophages, T and B cells, and dendritic cells (DCs).[23] As such, these innate immune receptors detect internalized microbial ligands including the Gram-negative peptidoglycan (PGN) derivative γ-C-glutamyl-meso-diaminopimelic acid and muramyldipeptide[24] which bind to NOD1 and NOD2, respectively.

LINKING INNATE AND ADAPTIVE IMMUNITY

Besides alerting the immune system of danger signals in the lumen, the innate system activates and coordinates adaptive immunity, which in turn, controls the composition and localization of components of the commensal microbiota. The secretory immune system, in particular sIgA, works in concert with innate components of the mucosal epithelium to limit colonization of the inner mucus layer (Figure 30-1)[8,11]. The production of sIgA depends on the intervention of innate immune cells and sometimes T helper cells.

Certain types of mucosal immune cells, like macrophages, are able to sample bacteria from the lumen of the gut and clear the bacteria which

have breached the epithelium layer.[25] The TLR-expressing DCs, are environmentally conditioned andare at the heart of the decision-making processes determining the outcome of the primary response in the intestine.[26] These mucosal DCs phagocytose a limited bacterial load from the lumen of the gut, migrate to the mesenteric lymph nodes and promote B and T cell[27] responses that result in the production of sIgA. Thedimeric IgA produced by plasma cells is then transported by the polymeric immunoglobulin receptor across the epithelium, out to the lumen of the gut.[28] In addition, DC supregulate their expression of major histocompatibility complex and costimulatory molecules following TLR engagement and in so doing, acquire the capacity to prime naïve T cells, which then develop into CD4+ T helper 1 (Th1), Th2, Th17, or T regulatory (Treg) effector cells.[26] The CD4+ lineage induced must allow effective defense, of appropriate magnitude, against any pathogen initiating the response yet keep autoimmune mechanisms under control.[29]

The CD4+ Th1/Th2 paradigm has dominated cellular immunity for several years. Th1 cells produce interferon (IFN)-γ, lymphotoxin and tumor necrosis factor(TNF)-α and protect against viruses and intracellular pathogens[29] whereas the Th2 subset secrete the signature cytokines IL-4 IL-5 and Il-13 and promote B cell antibody isotype switching to IgG1, IgA, and IgE. A number of observations suggest that exposure to IL-4 is essential for the priming of Th2 effector cells and that exposure to IL-12 is essential for the priming of Th1cells.[29]

The latest CD4+ T helper lineage to be identified, Th17, produces IL-17A, IL-17F, and IL-22. Th17 effector cells are critical mediators of immunity to bacterial and fungal infections at epithelial barriers and are present early in life.[30] However, Th17 effector cells can also be mediators of inflammatory processes.[31] Peripherally induced Treg development depends on extrinsic tissularsignals.[32] These cells mediate their effects via secretion of IL-10 or transforming growth factor (TGF)-β, and are thought to prevent autoimmune responses by specifically suppressing activation and proliferation of CD4 and CD8 effector T cells. The development of CD4 + effector and regulatory lineages is determined by the transcription factors the cells express and the genes they transcribe.[29] Clearly, DC play an important role in the choice of CD4+ lineage commitment.

Interestingly, recent studies have shown that not all commensals are equal in their capacity to interact with immune cells and to control the development and activation of regulatory or effector immune responses.[33] Segmented filamentous bacteria stimulate Th17 while Clostridia and the

polysaccharide A of *Bacteroides fragilis* stimulate Treg. However, the mechanisms behind these differential responses are, as yet, unknown.[34]

COMPONENTS OF THE NEONATAL INTESTINAL BARRIER

For successful colonization, healthy immune status and a beneficial relationship with the microbiota throughout life, the most elementary immunoregulatory mechanisms must already exist in the neonatal intestine at birth (Figure 30-1). Certainly, some immune instruction already begins prenatally and depends on the thymus for the generation of self-tolerant effector and regulatory T cells. Immature T cells interact with thymic epithelial cells in a vital process that ensures the maturation, differentiation, and selection processes of the mature T cell pool. These prenatal events explain the central features of adaptive immunity and self-tolerance already present at birth.[35] However, while it is important to restrict antigen exposure and actively down-regulate immune reactions *in utero* for fetal survival, this leads to deficits in innate and adaptive immunity in the newborn period. It takes several years before the immune system fully develops but in the immediate to early postnatal period, gestational age, and environmental factors have a profound impact on the maturation process. Indeed, there is clinical evidence that preterm infants are at great risk of infections associated with disorders of the gut ecology[36] and at higher risk of systemic infections due to intracellular pathogens.[37]

There is compelling evidence from animal studies that the symbiotic relationship between the host and the microbiota is critical to the normal development and maturation of the mucosae and their associated lymphoid tissues after birth.[38] Compared to specific pathogen-free animals, germ-free animals have less developed Peyer's patches and mesenteric lymph nodes; reduced numbers of intraepithelial lymphocytes, IgA-secreting cells and Paneth cells[39,40]; limited production of AMP as well as an attenuated mucus layer, in spite of a normal number of goblet cells.[41]

Secondary lymphoid tissues such as Peyer's patches and mesenteric lymph nodes are present prenatally in the developing intestine[40], but postnatal bacterial colonization is thoughtto initiate multiple events that promote the development and functional maturation of the gut associated lymphoid tissue (Figure 30-1).[20,40] For example, the recognition of PGNby NOD1 elicits the production of CCL20 and β-defensins that promote B cell recruitment to the mucosal lymphoid organs and induce expression of

sIgA.[42]

Both the numbers of Paneth cells and the expression of AMP are also developmentally regulated in humans and can already be detected in fetal intestine, at 24 weeks ofgestation.[41,43] However, the newborn intestine has a fewer number of Paneth cells and lower expression of AMP than adult intestine both of which most likely render the infant more susceptible to disease. The observation that Paneth cells of both preterm and term infants with necrotizing enterocolitis (NEC)do not express lysozyme, supports this hypothesis.[44]

Although the innate immune response is not considered to require previous immunological experience to be activated, the homeostatic mechanisms operating in the adult intestine are not expected of the naïve neonatal immune system, particularly if one considers that the same host receptors recognize both pathogens and non-pathogens. Indeed, the increased susceptibility of neonates to infection and certain allergens suggests that the capacity to handle antigenic challenge is not inherent but develops over time and/or through education and experience. In the immediate postnatal period, the cellular composition of the microbiota is highly variable as many organisms vie to colonize the mucosa. This physiological process can trigger an inflammatory response not only in the gut, but also systemically owing to the high permeability of the neonatal intestine. Remarkably, detrimental inflammatory reactions do not normally occur and immune homeostasis prevails.

Certainly, the neonatal intestine has the molecular machinery to recognize microbial conserved molecules. Postnatalintestinal exposure to bacterial product sresults in transcriptional activation in the epithelium and a transient inflammatory status.[41] As in the mature intestine, this is achieved through TLR mediated signal transduction. Effective control of the inflammatory process in the neonatal mucosa is critical for survival and involves different cell types and mechanisms such as low expression of TLR2 and TLR4 on IECs[20] and lamina propria cells and/or limited cellular signaling following engagement with non-pathogens.[24] However, the innate immune response determines the subsequent adaptive response —the choices made during CD4+ Th cell differentiation being of particular importance in the immature neonatal period. In the human newborn, they result in a strong bias toward Th2 and Th17 cell differentiation and a defect in Th1-polarizing cytokine production.[45] The net consequence of which is an increased vulnerability to intracellular pathogens but adequate defense against extracellular organisms, possibly to cope with the

transition from the sterile intrauterine environment to a contaminated extrauterine environment.

When non-pathogens come in contact with innate sentinel cells, transient IEC activation is followed by a tolerogenic, functional hyporesponsiveness. Several mechanisms seem to be involved in the development of this innate immune tolerance[41] which is characterized by down-regulation of TLR2 and TLR4 expression on IECs, and repression of the critical TLR signal transduction molecule, IRAK-1.

DEVELOPMENT OF THE INTESTINAL MICROBIOTA

The mature microbiota is composed of up to 40,000 bacterial species distributed in several phyla, the two most dominant being *Firmicutes* and *Bacteroidetes*. The gastrointestinal immune system has an influence on systemic immune function. Bacterial challenge is a major driving force for immune responses due to the broad diversity of bacterial haplotypes and derivedmolecules.[8,46] Approximately 80% of the body's immune cells are located in the intestine.

Humans start life in the aseptic intrauterine environment but at birth all epithelial surfaces are suddenly exposed to, and then colonized by, environmental microbes. Indeed, microbial colonization of newborn feces can be detected only a few hours after birth.[38] Neonatal intestinal colonization is a potentially hazardous process and yet, it is probably the most important factor influencing the development and maturation of the intestinal immune system and if successful, is fundamental for health throughout life. As discussed above, several simultaneously acting processes protect the neonatal mucosa from a massive inflammatory reaction during this process.[47]

The number and type of bacteria competing for, and colonizing the intestinal habitat, depends on host and environmental factors. During the first days of life, the intestinal microbiota undergoes major compositional changes until a steady state is reached at approximately 1 year of age.[38,48] The mode of delivery, the gestational age, exposure to antibiotics, hospitalization, and length of hospital stay, as well as the type of nutrition have all some bearing on the composition of the neonatal microbiota.

Intestinal colonization seems to be different between pre-term and full-term babies and may play a role in a variety of immune and inflammatory neonatal conditions such as NEC and gut-derived sepsis.[49] Indeed, an

inappropriately energetic inflammatory response towards intestinal microbes seems to be one of the pathogenic mechanisms at play in NEC.

The presence of oxygen and the positive redox potential of the neonatal intestine seem to favor the initial colonization by facultative anaerobes, Staphylococcus, Enterobacteriaceae, and Streptococcus being the most commonly isolated genera in newborn fecal flora soon after birth. Thereafter, strict anaerobes such as Bifidobacterium species and Clostridium species appear,[38] followed by other strict anaerobes such as Bacteroides and additional Clostridium species.[50] A recent study using state-of-the-art molecular methods has challenged this generally accepted view of microbial succession and has shown that total anaerobes already outnumber total facultative bacteria during the first week of life in breast-fed infants.[51] Further studies involving a higher number of infants will be required to clarify this controversial point.

The interplay between milk factors, the microbiota, and the neonatal immune system is complex and difficult to decipher but there is increasing evidence that the events taking place during the early stages of life impact immune function and health throughout the lifespan. The hygiene hypothesis, proposed to explain the rise in atopic diseases, suggested that early in life, microbial antigens interacting with the innate immune system tip adaptive immune responses toward a Th1, and away from a Th2 response.[52] A recent adaptation of this hypothesis proposes that instead of priming immune activation, such microbial stimulation primes immunoregulation via Treg cells and regulatory antigen presenting cells.[46] However, the capacity of the microbiota to promote genetic regulation of immune homeostasis via diverse mechanisms are only now being elucidated.[53]

Molecular studies have also enabled a deeper understanding of how environmental factors such as breast milk, influence neonatal intestinal colonization, and as a consequence, immune development. A recent study showed greater phylogenetic heterogeneity in the microbiota of healthy breast-fed infants compared to that of formula-fed babies.[54] Furthermore, while there is an undeniable preponderance of Bifidobacterium in the stools of breast-fed infants, Enterobacteria, coliforms, Clostridia, and Klebsiella are present at equivalent levels to Bifidobacterium in the stools of formula-fed babies.[55,56] Global intestinal epithelial gene activation also differs between the two populations.[54] It appears that virulence related genes of the microbiome trigger divergent genetic activation of immune defenses depending on whether infants are breast-fed or formula-fed. More

specifically, host genes that mediatebacterially induced reactive oxygen species signaling and epithelial homeostasis were up-regulated in breast-fed infants whereas genes that prime inflammatory mucosal responses were up- regulated in formula-fed babies. The greater incidence of infections, inflammation and allergy in formula-fed infants compared to breast-fed infants suggests that breast milk is a source of protective regulatory factors. Molecular studies will deepen our appreciation of not only the manner in which the microbiota shapes host immunity but the importance of breast milk and specific milk factors in determining mucosal gene activation during the colonization process.

BREAST MILK FACTORS MODULATING THE RESPONSE TO MICROBES AND SHAPING THE INTESTINAL MICROBIOTA

As there is a delay in stabilization of the intestinal microbiota and in the complete maturation of the immune system, much of the immunologic benefits of breast milk have been attributed to the passive protection that it provides.[57] It is apparent that although breast milk supplies a combination of protective factors, functional redundancy is not rare. Not only do several factors exhibit the same biological function, a single molecule can have a range of biological activities. This complexity and the change in the concentration of specific components as lactation proceeds are testimony to a dynamic biological fluid, the complete function of which has still to be fully appreciated.

Despite a normal, integrated luminal barrier, some components of the intestinal microbiota and some pathogens circumvent host defense mechanisms and enterinto contact with epithelial cells. Such encounters are likely to occur more frequently in an immature intestine, thus additional protective mechanisms are required to ensure epithelial barrier integrity and preservation of mucosal homeostasis. To compensate for developmental delays and poor endogenous production of protective molecules in the neonatal intestine, soluble factors in breast milk prevent microbial antigens, pathogenic or not, from reaching the cells in host tissues. Moreover, some factors through their bacteriostatic or bactericidal actions can define the nature of microbial antigens that succeed in interacting with the intestinal immune system (Table 30-1). Examples are milk oligosaccharides, glycans, MUCs[58] and AMP including defensins, cathelicidins, lysozyme, and lactoferrin and its peptides.[59]

TABLE 30-1 Examples of Human Milk Factors That Define the Intestinal Microbiota	
Oligosaccharides and glycoconjugates	Receptor analogues that inhibit binding of pathogens and their toxins to epithelial cells Bifidogenic effect
Mucin 1	Inhibits binding of S-fimbriated *E. coli* and rotavirus to epithelial cells
Lactadherin	Inhibits binding of rotavirus to epithelial cells
Defensins and cathelicidins	Bacterial killing via membrane disruption
Lactoferrin	Bacterial killing by lactoferricin peptide Bacteriostatic activity by binding ferric iron. Bifidogenic effect
Lysozyme	Bacterial killing via membrane disruption
Secretory IgA	Inhibits binding of pathogens to the intestinal mucosa. Facilitates biofilm formation by the normal flora. Bifidogenic effect of secretory component.
α-Lactalbumin	Anti-bacterial peptides
Fatty acids	Anti-bacterial activity

Trefoil factors (TFF), secretory products of goblet cells, also contribute to epithelial surface integrity and improve repair of damaged epithelium through a process called epithelial restitution.[60] It is not known if the neonatal intestine is able to produce TFF in sufficient quantities, but TFF are present in human milk[61] and while their contribution to neonatal intestinal development and protection against disease remain unknown, they have been shown experimentally to promote β-defensin production and down regulate the inflammatory response in human IECs.[62]

Closer scrutiny of the interplay among specific milk molecules, microbes, and the mucosal immune system is beginning to unravel some of the intricacies of breast milk protection. It is becoming apparent that exogenous factors in milk play a regulatory, or even an educational, role in the underlying immune processes. Simplistically, soluble factors in breast milk can interact directly with microbial cells to limit subsequent contact with the intestinal epithelium. However, the most recent research now suggests that breast milk permits, and indeed encourages, interaction between particular microbial motifs and the intestinal immune system[7] but curbs any energetic immunereaction.[63] In so doing, breast milk promotes a symbiotic relationship between the neonatal immune system and the various bacterial communities that constitute the permanent microbiota of

the gut.

Prebiotic and Antimicrobial Activities of Human Milk Oligosaccharides and Glycoconjugates

Human milk oligosaccharides (HMOs), a heterogeneous group of unconjugated compounds, are the third most abundant solidcomponent in breast milk after fat and lactose. Colostrum levels of HMOs can reach about 20 g/L but their concentration decreases as lactation proceeds.[64]

HMOs are synthesized by specific mammary gland glycosyltransferases, which sequentially add fucose, galactose, *N*-acetylglucosamine, and sialic acid to lactose.[65] HMOs are not nutrients for the neonate since infants lack the enzymes necessary for their digestion. Instead, they can pass undigested into the colon where they not only create an acidic environment that is antagonistic for pathogens, they stimulate the growth and metabolism of symbiotic bacteria, such as *Bifidobacterium*, that then compete with pathogens for occupation of intestinal niches.[66]

HMOs provide further protection through molecular mimicry. Pathogens such as *Streptococcus pneumoniae*, *Escherichia coli*, C*ampylobacter jejuni*, *Listeria monocytogenes*, *Shigella*, *Salmonella*, and *Vibrio cholera*, initiate the infectious process by adhering to oligosaccharides expressed on epithelial cell membranes.[67] In vitro, epidemiological and clinical studies suggest that by resembling structures on the mucosal cells, HMOs serve as decoy receptors for pathogen adhesion factors and thereby prevent pathogen binding to mucosal surfaces.[68] HMOs may also mediate their protective effects by modifying the composition of the glycocalyx or the expression of glycoproteins on the epithelial surface,[69] as well as modifying bacterial genes involved in host-microbe interactions.[70] Certainly, the important concentrations of 1, 2-linked fucosylated glycans in human milk have been shown to protect breast-fed infants against diarrhea caused by campylobacter, caliciviruses, and the stable toxin of enterotoxigenic *E. coli*, as well as against other etiologies of moderate-to-severe diarrhea.[71]

While HMOs are bifidogenic, it is not known if they have a more global influence on the composition of the neonatal microbiota. Nevertheless, the observation that breast-fed infants harbor less P-fimbriated *E. coli* than type 1 fimbriated *E. coli* and are less likely to suffer from urinary infections,[72] would suggest that a more global effect on the microbiota is indeed plausible.

There is an increasing body of evidence that HMOs can also modify

the activity of epithelial and immune cells and as such, can exert immunomodulatory properties at the mucosal or systemic levels.[67] Many of the observations have been made *in vitro* and the clinical relevance remains speculative, nevertheless, HMOs promote *Bifidobacterium*-mediated expression of tight junction proteins and anti-inflammatory cytokines by IECsas well asencourage lymphocyte maturation and activation.[73] Furthermore, by interacting with immunomodulatory lectins such as galectins, which influence T helper cell development and inflammation[74] and with selectins, which regulate leukocyte migration and the inflammatory response,[67] HMOs may exert additional, currently unknown, indirect effects on the immune status of the neonate. Irrespective of the mechanism, studies in animal models support the contention that HMOs are important breast milk factors in the prevention of NEC.[75]

Milk also contains several glycoconjugates which confer protection on the suckling neonate. The milk fat globule membrane glycoproteins, MUC-1 and lactadherin, inhibit rotavirus replication and prevent experimental gastroenteritis through their sialic acid residues.[76] Several other glycoconjugates of human milk are now known and include the ganglioside GM1, which binds to cholera toxin and labile toxins of *E. coli* and *C. jejuni*; the neutral glycolipids globotriaosylceramide, which binds to toxins of *Shigella* and *E. coli*; a mannosylated glycoprotein that inhibits binding of some strains of *E.coli* to human intestinal epithelium; and finally, glycosaminoglycans, which inhibit binding of the outer membrane protein of the AIDS virus to CD4 T cells.[77]

Antimicrobial Proteins and Peptides

The presence of an exogenous source of AMP in human breast milk may compensate for the deficit in Paneth cells and AMP observed in the immature neonatal intestine. The presence of multiple molecules with antimicrobial activity has been reported in human milk including lysozyme,[78] defensins[79] and cathelicidin.[80] They are produced by mammary gland epithelial cells and milk cells,[81] are present in milk in significant concentrations throughout lactation, and have demonstrable antimicrobial activity against a broad range of microorganisms.

Lactoferrin is a major protein of breast milk. It is present throughout lactation and has multiple biological effects.[65] By virtue of its iron binding properties, lactoferrin has been proposed to play a role in iron uptake by the intestinal mucosa and to act as a bacteriostatic agent by withholding iron from iron-requiring bacteria.[82] An antimicrobial effect of lactoferrin,

independent of the degree of iron saturation, has also been described and may be due to the generation of the bactericidal peptide, lactoferricin, during digestion.[83] However, lactoferrin is relatively stable in the neonatal intestine and can be found intact or partially hydrolyzed in the feces of suckling but not formula-fed infants.[84] Interestingly, lactoferrin[85] and its peptides have been shown to promote growth of lactic acid bacteria such as *Bifidobacterium* and *Lactobacillus*. There have been some promising clinical studies which have also shown a beneficial effect of recombinant human lactoferrin in the prevention of NEC.[86] Moreover the use of bovine milk lactoferrinseems to prevent late-onset sepsis and NEC in preterm infants when given in combination with a probiotic microorganism.[87]

Immunoglobulins

Although intestinal lymphoid structures are present at birth, immunoglobulin-producing B cells are not fully operational for several weeks.[40] This delay in B cell activation and maturation into antibody–producing plasma cells causes a transient deficit in secretory IgA (sIgA) production and reduced protection of the neonatal intestinal mucosa.[88] Microbial colonization of neonatal tissues leads to B cell activation by 1 month postpartum. The B lymphoblaststhen mature into plasma cells that produce polymeric IgM and, most frequently, dimeric IgA, which are transported across the intestinal epithelium by polymeric immunoglobulin receptors.[89]

In the early newborn period, breast milk-derived antibodies compensate for the deficit in neonatal production. These milk antibodies are produced in the mammary gland by the B lymphoblasts that have trafficked from maternal gastrointestinal and bronchial lymphoid tissues to the mammary gland.[90] The repertoire of milk antibody specificity is governed by environmental antigens, including the infectious agents to which the mother has been exposed,[91] and can be directed against both enteric and respiratory pathogens, including viruses. Concentrations of sIgA are higher in the feces of breast-fed infants than in those of formula-fed infants[92] and may reflect the capacity of milk sIgA to resist gastrointestinal digestion.

The dominant immunoglobulin in human milk is sIgA, which protects neonatal mucosal surfaces by a mechanism called “immune exclusion” This involves agglutination and immobilization of different pathogens,[93] including viruses, bacteria, and parasites as well as neutralization of endotoxin and other bacterial products. In so doing, sIgA prevents their

interaction with the intestinal epithelium and facilitates their elimination by peristalsis, without triggering inflammatory tissue damage.[28,91,93] Although, many bacteria in the intestinal microbiota are coated with sIgA, they are not permanently eliminated from the intestine.[94] The reasons for this apparent inconsistency are not known but may be related to the type and specificity of the antibody.

Paradoxically, sIgA binds to M cells of the intestinal Peyer's patches and then to underlying DC and, as a consequence, facilitates transport of microbes and antigens to the mucosal immune system.[95] It is tempting to speculate that milk sIgA uses this mechanism to educate the neonatal immune system in the management of commensal microbiota and pathogens. Certainly, physiological transport of microbesfrom the gut lumen to the mesenteric nodes has been described as an important process in immune homeostasis.[27]

EDUCATION OF THE MUCOSAL IMMUNE SYSTEM BY FACTORS IN BREAST MILK

Protection and education of offspring are integral parts of evolutionary success, and breast milk composition has adapted to meet these requirements. However, while the passive protection afforded by breast milk is well recognized, the manner by which it educates the neonatal immune system is less obvious. There is certainly accumulating evidence to suggest that the effects of breast milk extend beyond the neonatal period and that there is a more intimate association between maternally derived milk factors and the neonatal immune system, beyond that required to prevent pathogen colonization and infection. The mechanisms underlying the long-lasting benefits of breast milk are likely to be multifarious. At least two different and partially overlapping processes are probably involved:

1. First, breast milk factors, in shaping the composition of the neonatal microbiota, indirectly influence immune system development and response.[51,96] Breast milk contains a myriad of factors that, qualitatively or quantitatively, may modulate how neonatal cells perceive microbes and/or react to microbial contact. Examples are immunoglobulins, oligosaccharides, glycoproteins and glycolipids, which interfere with bacterial binding to epithelial cells, and AMP, which limit bacterial challenge and encourage the preponderance of particular

microbial species. In addition, breast milk-derived bacteria may be a preferential inoculum to build up the neonatal microbiota.[96,97]

2. Second, breast milk directly "educates" the neonatal immune system to react with appropriate innate or adaptive immune responses upon microbial or antigenic challenge. It can modulate the homeostatic balance between tolerogenic and effector immune responses and influence the development of pathologic diseases later in life.[5]

A crucial role for breast milk in the induction of immunological tolerance to exogenous and endogenous antigens and in the prevention of pathological conditions later in life, is gaining credence. The tolerogeniccapacity of breast milk is mediated by different mechanisms including (a) the transmission of antigens from the maternal environment to the suckling newborn via breast milk and, (b) the presence of immunomodulatory factors in breast milk.[63] Indeed, simultaneous exposure to antigens potentially involved in human pathological processes, together with immunomodulatory factors in the milk,[6,63] may be explain the protection breast milk provides against immune-mediated diseases such as allergy, Type 1 diabetes mellitus and celiac disease.[63,98] Furthermore, it is feasible that exogenous and maternal self- antigens in breast milk may prevent such diseases through antigen-specific induction of immunological tolerance. Certainly, maternal exposure to environmental antigens leads to the formation of immune complexes which are transferred to the infant via the milk and then educate the neonatal immune system to remain tolerant to the antigen.[99]

IMMUNE EDUCATION BY BREAST MILK DURING NEONATAL INTESTINAL COLONIZATION

Through their immunomodulatory activity, milk growth factors and cytokines may affect neonatal immune development, but arguably, the finest education is achieved through experience. To this end, milk limits, but does not completely veto, bacterial interaction with the mucosal surface and the intestinal immune system. Indeed, such interactions are important for postnatal maturation of intestinal immunity[33] and any delay to this maturation, such as that caused by reduced microbial stimulation,

may increase susceptibility to allergic disease.[46] The following sections discuss how milk may modulate microbial interactions with receptors on host cells, thereby encouraging cellular activation to particular microbial motifs but prevent crude, exaggerated inflammatory responses that may occur more readily in immature cells.

PRR–Bacteria Interactions in the Presence of Breast Milk

Lipopolysaccharide of gram-negative bacteria is a potent stimulator of the innate immune response, but it requires several host humoral and cell-surface proteins to mediate its effects. These include the acute-phase lipopolysaccharide (LPS)-binding protein (LBP), and the glycoproteins CD14, TLR4, and myeloid differentiation protein (MD)–2.[100] Cellular activation begins when LPS binds to LBP, which subsequently accelerates LPS binding to CD14 on the cell surface. LPS is then transferred from the CD14–LBP complex to a cell surface TLR4–MD-2 complex, which transduces intracellular signaling. In contrast, cellular activation by the lipoteichoic acid (LTA) of gram-positive bacteria involves TLR2-mediated signals.[101]

TABLE 30-2 Examples of Human Milk Factors That Modulate Responses to Bacteria

Soluble CD14	Transfers lipopolysaccharide and lipoteichoic acid to TLR complexes or to lipoproteins Modulates TLR signaling. Pro-inflammatory
Soluble TLR2	Modulates TLR signaling. Anti-inflammatory
Lactoferrin	Modulates TLR signaling Anti-inflammatory
Interleukin-10	Increases expression of CD14 Anti-inflammatory
Transforming Growth Factor-β	Decreases expression of CD14 and TLR4 Anti-inflammatory
Osteoprotegerin	Anti-inflammatory
β-Defensin 2	Activates dendritic cells and induces Th1 immune responses via TLR4

Human breast milk contains high levels of soluble forms of CD14 (sCD14)[7,102] and TLR2[103] which, like lactoferrin, may modulate TLR

signaling (Table 30-2). Depending on its concentration and environment, sCD14 can activate or inhibit responses to LPS by respectively transferring LPS to, or diverting LPS away from,[104] membrane CD14 (mCD14). Furthermore, sCD14 can transfer LPS directly to the TLR4–MD2 receptor complex in cells that lack mCD14, such as endothelial and epithelial cells[105].

It is feasible, therefore, that the ambivalent nature of sCD14 allows physiological activation of cells for homeostasis is but prevents exaggerated inflammation during infection or sepsis. Further assurance may be provided by additional milk proteins that bind sCD14 and lessen sCD14–LPS or sCD14-bacteriallipoprotein(BLP)-mediated cell activation. An example of the former is the AMP lactoferr in that binds specifically, and with high affinity, to the lipid A region of LPS[106] as well as to sCD14 and the sCD14–LPS complex.[107] The more recently discovered sTLR2 also decreases in concentration over the lactation period and, by binding to sCD14 in milk, has been postulated to moderate responses to bacterial lipopeptide and gram-positive bacteria.[103]

Thus, some receptors in cell-surface TLR complexes exist as soluble forms in milk and act as decoy receptors for microbial motifs (Table 30-2). Still other proteins found in milk, such as IL-10 and TGF-β, at constant levels throughout the first months of lactation, may modify TLR-mediated responses by regulating the expression of the various proteins in the TLR receptor complex. In this respect, IL-10 increases the expression of CD14 on monocytes but does not alter their expression of TLR-4.[108] In contrast, TGF-β down regulates the expression of CD14 on macrophages.[109] Importantly, TGF-β null-mice have increased TLR4 expression and inflammatory lesions in multiple tissues.[110]

Cellular Reactivity to Bacteria in the Presence of Breast Milk

The predominant production of Th2 cytokines in fetal and neonatal life is a key element in depressing innate immune responses in the newborn.[52] This deficiency in response results in impaired LPS-induced production of the pro-inflammatory, Th1-polarizing cytokines TNF-α, IFN-γ,[111] and IL-12 by neonatal mononuclear cells. An increased ratio of IL-6/TNF-α further polarizes toward a Th2 response.[112] It follows that low expression of TLR2 and TLR4 in the neonatal intestinal epithelium together with no expression of MD2[113] may explain hyporeactivity to components of the

microbiota.[20] In contrast to neonatal mononuclear cells and adult IECs, human fetal enterocytes express TLR2 and TLR4 and are hyper-responsive to LPS.[114] This hyper-reactivity may also depend on a lower expression of the inhibitory intracellular molecule I-κBα, which binds NF-κB and retains it in the cytosol.[115]

The interaction between luminal microbes and highly expressed TLR4 on neonatal IECs may represent a risk factor for the development of NEC.[114] Thus, increased TLR expression on human fetal enterocytes could explain the increased susceptibility of premature infants to NEC. Nevertheless, a transient activation of IECs, with IκB-α phosphorylation and subsequent NF-κB nuclear translocation, may be required for subsequent postnatal tolerance toendotoxin.[116]. Indeed, continuous activation in the presence of bacterial ligands is then thought to down-regulate TLR expression on IECs,[113] perhaps via shedding of the receptors.[103]

Remarkably, the presence of soluble PRRs and their partners in breast milk may participate in both the transient activation of innate immunity and in its subsequent down regulation. Certainly, milk sCD14 mediates the production of pro-inflammatory cytokines IL-8 and TNF-α, and of the chemokine ENA-78, by IECs exposed to LPS,[7] as well as the production of IL-8 in monocytes and DCs exposed to LPS.[117] At first glance, it is difficult to reconcile why high levels of sCD14 in breast milk, in the presence of an important bacterial inoculum, do not lead to excessive inflammation in the intestine. One possible explanation is that strong activation leads to shedding of the TLR involved in the response.[103] However, it is also possible that other proteins in milk refine the response by interacting with sCD14 or sCD14 complexes as described earlier. An example is lactoferrin, which in addition to downregulating LPS-induced production of pro-inflammatory cytokines via NF-κB, also inhibits sCD14–LPS-induced expression of IL-8 by human endothelial cells as well as their increased expression of adhesion molecules, E-selectin and intercellular adhesion molecule (ICAM)-1.[118]

It is also noteworthy that the TLR2 ligand LTA does not stimulate pro-inflammatory cytokine production by IECs in the presence of milk, but rather inhibits sCD14-mediated LPS effects.[119] This observation suggests that gram-positive bacteria, via their LTA, may moderate cellular reactivity to LPS. However, more recent work has shown that sTLR2 in human milk can bind sCD14 and that sTLR2 can inhibit monocyte production of IL-8 and TNF-α in response to synthetic bacterial

lipopeptide.[103] It is now known that multiple rounds of NF-κB activation are necessary in a first instance for immune defense and thereafter, for resolution of inflammation and tissue repair, and that the latter is achieved through IKK-α inhibition of NF-κB.[120] It is becoming apparent that breast milk has evolved to provide molecules that act at several levels of this process. First, it permits the neonate to mount a limited response to the microbial "danger" signal by promoting the production of pro-inflammatory cytokines. Thereafter, it may activate a second set of genes that are be part of a negative feedback mechanism.[117]

Perhaps as a precautionary measure, breast milk already provides anti-inflammatory factors and AMP whose expression in the neonatal mucosa would otherwise require additional NF-κB activation (Table 30-2).[79] In agreement with this, a certain ambivalence is seen with some milk factors such as TGF-β,[121] sCD14[7] and the antimicrobial factors lactoferrin and lysozyme, which have the capacity to activate or inhibit NF-κB activation depending on the concentration and the cellular environment.[82]

The TRAF6 signal transducer of the TLR/IL-1R superfamily is also important for signaling of the receptor activator of NF-κB (RANK) and its ligand (RANKL),[122] both of which are key regulators of lymph node formation and T cell–DC crosstalk. Osteoprotegerin (OPG), a natural, soluble decoy receptor for RANKL, is expressed by human mammary gland and breast milk cells, is present in human breast milk for at least the first six months postpartum and can be detected in the serum of neonatal animals after gavage. OPG is also expressed by IECs and is upregulated in the tissues of inflammatory bowel disease patients.[123]

Maternal milk also inhibits IL-1β–induced NF-κB signaling in human IECs in vitro, perhaps due to the presence of the IL-1 receptor antagonist (IL-1ra) whose levels persist throughoutlactation.[124] Certainly, both human milk and an infant formula supplemented with humanIL-1ra, have anti-inflammatory effects on chemically induced colitis in rats.[125] Soluble TNF-α receptor[124] and IL-10[126] in milk may behave in a similar manner.

As well as being a fuel for bacteria, HMO may also keep the reactivity of the neonatal immune response in check. They can interfere in protein–carbohydrate interactions, such as those mediated by selectins, and can inhibit formation of platelet–neutrophil complexes and the subsequent transmigration of neutrophils through activated endothelium at sites of inflammation.[67]

Education of the Neonatal Immune System via Microbes

in Milk

A variety of viable leukocytes are found in human milk but their concentration declines as lactation proceeds.[127] These leukocytes are cells that have migrated from the maternal gut- and bronchial-associated lymphoid tissue to the lactating mammary gland via the lymphatics and the circulation.[128] The cell populations include granulocytes, macrophages, and lymphocytes, predominantly T cells. A significant proportion of the latter being $CD8^+$ effector cells that may be important in the control of viral passage from mother to infant.[4]

Ingested milk leukocytes may survive gastrointestinal passage and a small number may be taken up by the neonatal intestinal barrier and migrate to the mesenteric lymph nodes.[127] Macrophages and granulocytes are considered to be the predominant cell types. However, work demonstrating that $CD14^+$ milk mononuclear cells express HLA-DR, CD86, CD83, and DC-specific ICAM-3–grabbing non integrin suggests that these cells may, in fact, be partially differentiated DCs.[129] These cells are probably the source of some of the soluble factors in milk such as sCD14 and OPG, as well as several cytokines and chemokines.[130] Furthermore, they contain ingested IgA, which they may release upon encountering bacteria in the gut.[128]

In addition to maternal eukaryotic cells, there is accumulating evidence that bacteria of maternal origin are also transmitted to the infant via colostrum and breast milk.[1,96,97] Previously, most studies on the microbiology of human milk addressed the transmission of pathogens or contaminating commensals in samples meant for milk banks.[131] Recently, it has been suggested that breast milk is not sterile, even when collected aseptically. Rather, it is a natural source of diverse microorganisms that may be beneficial to the health of the suckling infant. Indeed, *Staphylococcus*, *Streptococcus*, and *Lactobacillus* species are readily identified. However, culture-independent techniques reveal a rich biodiversity of microbes also comprising *Enterococcus*, *Bifidobacterium*, *Corynebacterium*, *Propionibacterium*, *Peptostreptococcus*, and *Escherichia* species, amongst others.[96] The majority of milk organisms arise from the mother's skin or the infant's mouth. However, it has been postulated that cells migrating from the maternal gut-associated lymphoid tissue to the lactating breast, capture components of the luminal microbiota prior to their departure and transfer them to the suckling infant via breast milk.[132]

The relevance of the milk microbiome to infant health is not, as yet,

known but it may represent an inoculum for the development of the neonatal microbiota. Certainly, some species are common to a mother's breast milk and her infant feces.[96,133] Moreover, the milk microbiome may educate the neonatal immune system and confer protection. Indeed, there have been studies to suggest that *Bifidobacterium* strains isolated from human milk have probiotic properties such as antimicrobial and anti-inflammatory activities, anti-allergic effects and immunomodulatory activity and that they can improve gastrointestinal function.[134]

Together, these studies indicate that milk bacteria are not contaminants and suggest that the milk microbiome is influenced by several factors that significantly skew its composition. As breast milk bacteria are among the first microbes entering the human body, current data emphasize the necessity to understand the biological role that the milk microbiome may play in human health.[135]

Immune Education by Milk TGF-β

TGF-β is a multifunctional cytokine that inhibits the development of exaggerated responses to self or non-harmful antigens without compromising immune responses to pathogens.[121] It controls the initiation and resolution of inflammation through the regulation and survival of multiple cell types and together with IL-2, induces the differentiation of peripheral Treg from naïve CD4+ T cells. In addition, TGF-β regulates inflammation, oral tolerance, induction of IgA production and barrier function in the intestine.[121,136] There are several studies to suggest that exogenous TGF-β in milk may also have these effects in the host.

There are three isoforms of TGF-β: TGF-β1, TGF-β2, and TGF-β3 but TGF-β2 is the most abundant isoform in breast milk. It has been demonstrated that the intestine of premature human infants, particularly those experiencing NEC, express higher levels of pro-inflammatory cytokines and lower expression of TGF-β2 when compared to the intestine of full-term infants.[137] The same group also showed that orally administered recombinant TGF-β2 provides protection against inflammatory mucosal injury in an animal model of NEC. Together, these results support the hypothesis that an exogenous source of TGF-β in breast milk may be important for intestinal homeostasis in the neonate and may offer protection against immune-mediated disease. Further support for this is provided by a recent review that has evaluated animal studies addressing the capacity of milk TGF-β to influence immune responses in various experimental models.[138] Various studies suggest that milk TGF-β survives

passage through the digestive system and can be taken up by the neonatal intestine to exert effects in extraintestinal tissues. It can protect against endotoxic shock and exaggerated inflammatory responses. Furthermore, it induces oral tolerance in the host. It has been shown that airborne allergens are transferred from the mother to the suckling neonate[139] and that simultaneous exposure of neonatal animals to the allergen and TGF-β in the milk leads to oral tolerance induction and antigen-specific protection from allergic airway disease. This protective effect is mediated by regulatory CD4+ T lymphocytes and is dependent on TGF-β1 signaling in T cells. Together, the various studies suggest a role for milk TGF-β in influencing neonatal immune responses. Indeed, a correlation has been observed between TGF-β levels in breast milk and serum IgA levels in human newborn infants.[140]

Breast Milk Effects on Adaptive Immunity

As mentioned above neonates are susceptible to microbial infections and mount poor adaptive immune responses. The reasons for this are multifactorial and may include a lack of memory B and T cells and reduced T cell responses,[141] reduced numbers and maturation of DCs,[142] a high proportion of Treg cells but with naïve phenotype, and a bias toward Th2 immune responses.[143] However, specific TLR stimulation can overcome some of these defects[142] and may inhibit the developmentof Th2 responses.[144]

Breast-fed infants are less prone to develop asthma, atopic dermatitis, eczema, and allergy than formula-fed infants. Some studies have reported a correlation between the development of these diseases and the concentration of milk molecules sCD14, TGF-β, and sIgA.[145] Mechanistic studies certainly support a regulatory role for milk molecules in adaptive immunity and in correcting imbalances in Th17, Th1, Th2 and Treg responses. For example, sCD14 mediates LPS-induced TNF-α, IL-6, IL-8, and IL-12 release by DCs, as well as their expression of costimulatorymolecules.[146] Furthermore, it acts directly on activated human T cells to inhibit IL-2 production and cell proliferation, as well as the production of another Th1-like cytokine, IFN-β, and a Th2-like cytokine, IL-4.[147] Direct interaction of sCD14 with B cells, resulting in higher levels of IgG1 and marked inhibition of IgE production, has also been observed.[148] Consistent with these observations, administration of milk sCD14 to neonatal mice enhances antibody secretion.[102]

Several *in vitro* and *in vivo* studies have now demonstrated a role for

lactoferrin in T cell differentiation and the capacity of orally administered lactoferrin to correct the Th1/Th2 cytokine imbalance in both Th1 and Th2 models of disease.[149]

Studies in OPG null mice have shown that OPG regulates B cell maturation and the development ofefficient antibody responses.[150] It is also note worthy that Peyer's patch DCs express RANK and that treatment with antagonists of RANKL enhances the induction of tolerogenic immuneresponses.[151] It is feasible therefore that the high levels of OPG in milk may mediate similar effects.

HMO, specifically the Lewis X component, can interact with DCs via the cell-surface molecule dendriticcell-specific intercellular adhesion moleculegrabbingnon-integrin (DC-SIGN).[152] DC-SIGN is implicated in various functions, mainly related to pathogen recognition and antigen processing and presentation to CD4+lymphocytes, and can function both as an adhesion receptor and as a phagocyticpathogen-recognition receptor, similar to theTLRs.[153] Although likely, more studies are required to determine whether HMO interference with the interaction of DC-CD4+ cell interactions render the newborn host tolerant to components of the microbiota.

Other Protective Factors in Milk

Additional immunomodulatory factors in milk may regulate innate and/or adaptive immune responses. These include the antimicrobial β-defensin which induces cytokines and chemokines, is chemotactic for DCs, and uses TLR4 to activate DCs and induce Th1 immune responses.[154] Numerous cytokines and chemokines, such as IL-1β, IL-6, and TNF-α, monocyte colony stimulating factor, monocyte chemotactic protein 1, IL-8, and RANTES, as well as fatty acids, have also been described.[124,126] α-Lactalbumin is a major milk protein in all mammals. Its digestion provides a source of biologically important amino acids, AMP, and an immunomodulatory peptide that enhances macrophage phagocytic activity. Milk is also a rich source of hormones and growth factors that may aid nutrient transport and the growth and differentiation of neonatal tissues.[6]

CONCLUSION

Breast milk provides a well-recognized passive protection against pathogens in the neonatal period. However, recently discovered functions suggest that protection extends beyond the newborn period. The cocktail

of biologically active factors that milk provides, targets neonatal innate and adaptive immune responses at multiple levels. Milk's primordial task is to alert the innate arm of potential danger. To do so, it supplies molecules that actively promote a pro-inflammatory primary response upon exposure to antigens or microbial components. However, as a pivotal link between innate and adaptive immunity, it ultimately instructs the neonatal immune system to remain tolerant to nonthreatening antigens and components of the commensal microbiota, but to eliminate potential pathogens. To achieve this, it already provides a variety of anti-inflammatory factors that would otherwise imply further activation of neonatal cells. These additional factors fine-tune the type and level of reactivity. Differences between breast-fed and formula-fed infants suggest that in some infant formulas, certain elements needed for the control of these processes are lacking and the infant is more susceptible to antigenic challenge.

Approach to Breastfeeding

31

Robert M. Lawrence, MD, FAAP, FABM and Ruth A. Lawrence, MD, FAAP, FABM, FAAC

There are various memorable phrases and taglines associated with initiatives and campaigns to promote breastfeeding; “Babies were born to be breast-fed,” “Mother’s milk is never forgotten,” “Good health begins with breastfeeding,” or “Breastfeeding is more than just good nutrition.” The Fourth Annual Summit on Breastfeeding held in Washington, DC in June of 2012 was titled “First Food: The Essential Role of Breastfeeding.”[1–5] This chapter and others within this text provides knowledge and understanding to support these statements.

The “Breastfeeding Report Card” for the United States presented by the Centers for Disease Control and Prevention (CDCP) in 2012 reports that the average national rates for breastfeeding initiation reached 76.9%, breastfeeding at 6 months of age was at 47.2% and at 12 months at 25.5% and exclusive breastfeeding averages reached 36% at 3 months and 16.3% at 6 months in 2009.[6] The health goals of our nation for 2020 include a statement regarding breastfeeding. The goals particularly address high-risk women, those from minority, low-income, and undereducated groups.[2] The objectives focus on increasing the proportion of infants who are breastfed, for all infants, with targets of 81.9% for ever breastfeeding, 60.6% breastfeeding at 6 months and 34.1% at 12 months and exclusive breastfeeding through three months of 46.2% and through 6 months of 25.5%.[7]

The Institute of Medicine issued a report on nutrition during lactation as part of a review of nutrition in the perinatal period that stated that breastfeeding was ideal for all infants under ordinary circumstances.[8] It further stated that even women without perfect diets could produce good

milk and nourish their young well. Professional medical associations such as the American Academy of Pediatrics,[9] the American College of Obstetrics and Gynecology, and the Academy of Family Practice have developed policies encouraging universal breastfeeding. The World Health Organization and United Nations International Children's Emergency Fund (UNICEF) have taken very strong positions in support of worldwide breastfeeding, including the development of the Baby Friendly Hospital Initiative.[10,11]

Human milk is specifically designed for the needs of the human infant. Its nutritional advantages have been noted to be especially important for brain growth.[12–14] In the first year of life, the brain of the human infant doubles in size.[15] The myelinization of nerves is equally as important and occurs extensively in the first year of life. Taurine, cholesterol, and omega fatty acids are essential to brain growth and are uniquely present in human milk.[16]

Data from evidence-based systematic review and meta-analyses demonstrate clear benefits for breastfeeding infants and mothers in developed countries.[17,18] The benefits for the infants include a reduced risk of acute otitis media, severe lower respiratory tract infections, non-specific gastroenteritis, atopic dermatitis, asthma in young children, obesity, type 1 and 2 diabetes, childhood leukemia, and necrotizing enterocolitis. A history of lactation for women showed a reduced risk of type 2 diabetes and breast and ovarian cancer.[17,18]

The presence of dozens of active enzymes, the immunologic properties, infection protection properties, and allergy protection are some of the compelling reasons breastfeeding is superior for human infants.[19–22]

The number of women who elect to breastfeed has continued to increase, and the renaissance of breastfeeding is well established.[6,23] It is important for the clinician to be knowledgeable about the value of human milk, the advantages of breastfeeding, the clinical management of lactation, and the diagnosis and treatment of problems.[24] The current scientific literature provides a large resource of information on these topics, which will be summarized here.

ANATOMY AND PHYSIOLOGY

Lactation is the completion of the normal reproductive cycle. It is a physiologic process triggered by the termination of pregnancy, but anticipated both anatomically and physiologically from early

development.[16]

The breast bud is present at birth in both sexes, but remains dormant until early pubescence, when growth is stimulated by the increase in estrogen and progesterone in the female.[25,26] The ductal system proliferates and the breast matures. This maturation continues with stimulus from each menstrual cycle until age 25. When growth stabilizes, further proliferation does not occur until pregnancy intervenes (Figure 31-1).

Changes in circulating hormones result in profound changes in the ductular-lobular-alveolar growth during pregnancy.[27] There is marked increase in ductular sprouting, branching, and lobular formation evoked by luteal and placental hormones (Figure 31-2). Placental lactogen, prolactin, and chorionic gonadotropin have been identified as contributors to the accelerated growth.

From the third month of gestation, secretory material resembling colostrum appears in the alveoli. By the second trimester, placental lactogen begins to stimulate the production of colostrum so that a women delivering immaturely as early as 16 weeks may secrete colostrum although her baby is not viable. Until delivery, the production of milk is suppressed by prolactin-inhibiting hormone (PIH) produced by the placenta. Progesterone produced by the placenta has been recognized as important in blocking milk production in pregnancy. At delivery, the withdrawal of placental and luteal sex hormones and the infant’s sucking result in the loss of the inhibiting hormones and the stimulation of prolactin releasing factors.[28]

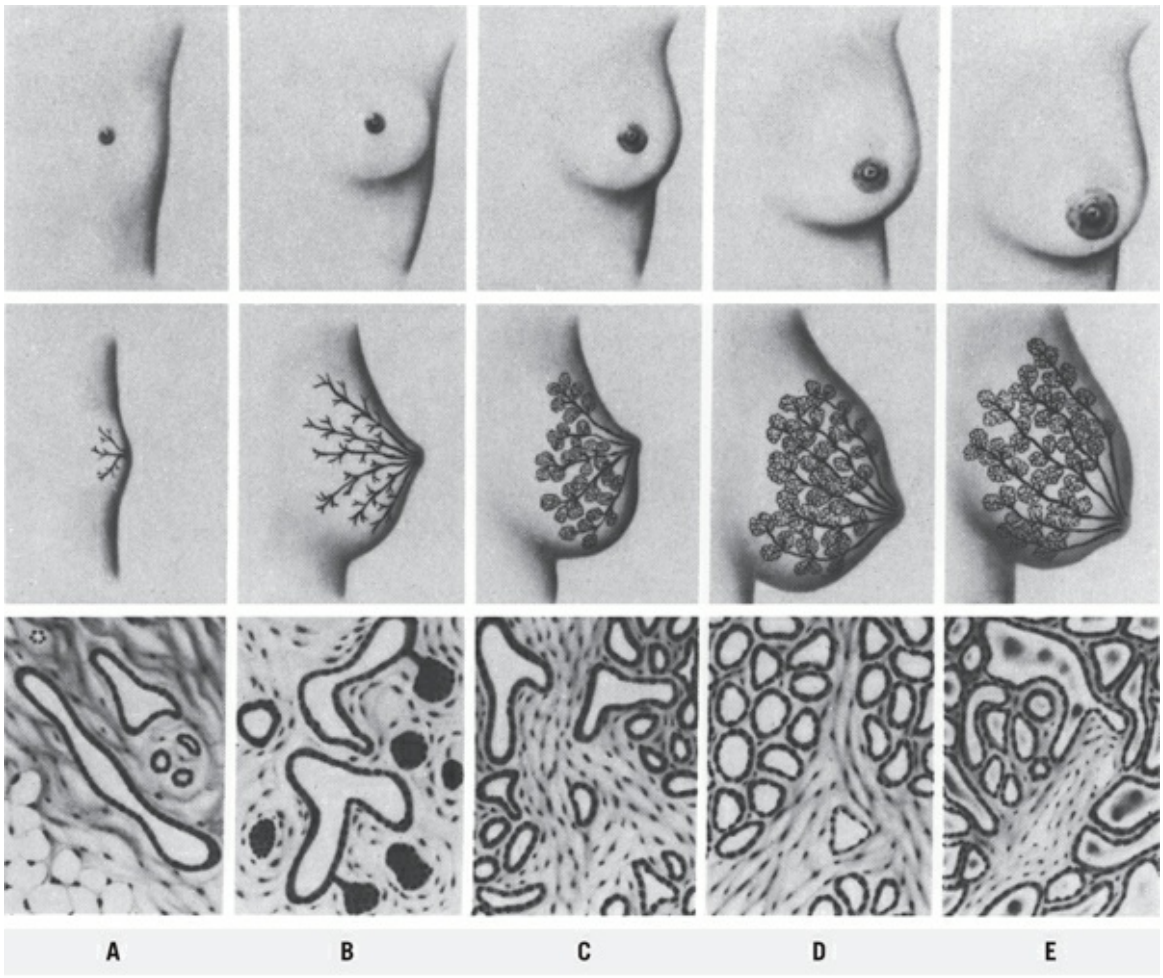

Figure 31-1 Female breast from infancy to lactation with corresponding cross-section and duct structure. *A, B, C,* Gradual development of well-differentiated ductular and peripheral lobular-alveolar system. *D*, Ductular sprouting and intensified peripheral lobular-alveolar development in pregnancy Glandular luminal cells begin actively synthesizing milk fat and proteins near term. Only small amounts are released into lumen *E*, With postpartum withdrawal of luteal and placental sex steroids and placental lactogen, prolactin is able to induce full secretory activity of alveolar cells and release of milk into alveoli and smaller ducts. Reproduced with permission from Lawrence and Lawrence.[10]

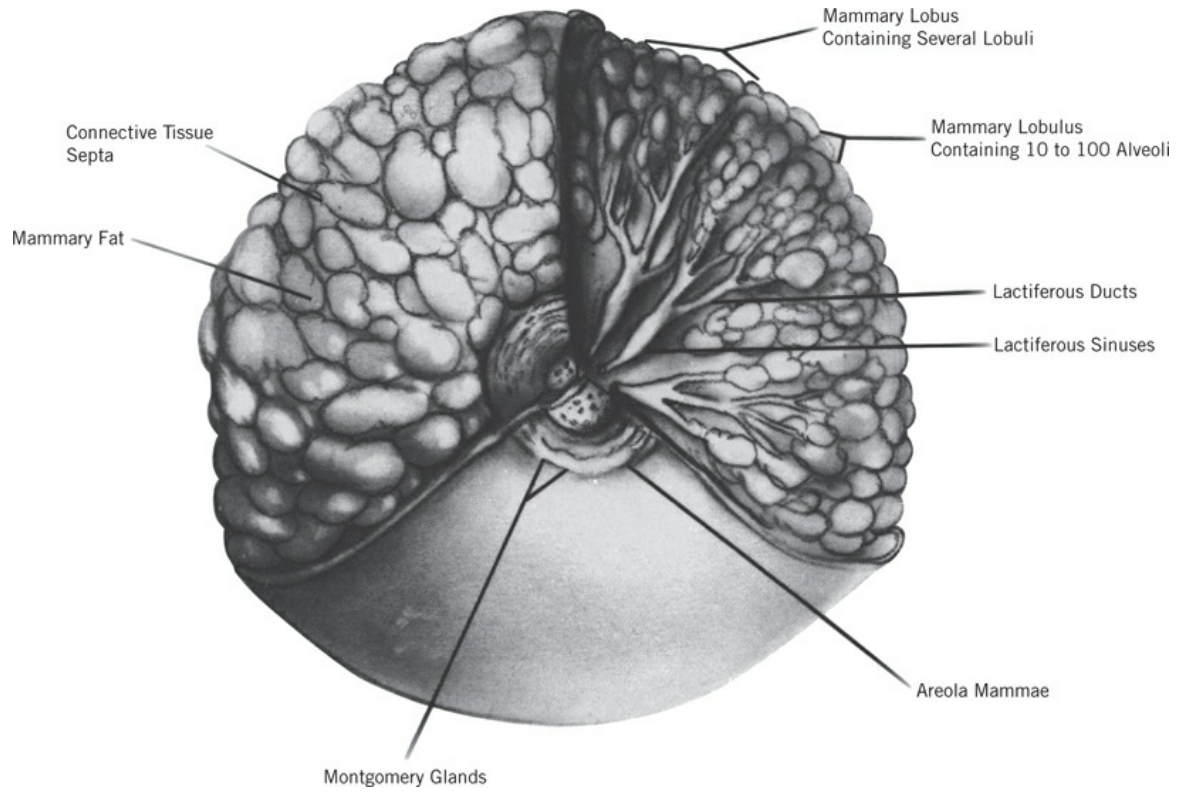

Figure 31-2 Morphology of mature breast with dissection to reveal mammary fat and duct system. Reproduced with permission from Lawrence and Lawrence.[10]

The initiation of milk secretion at delivery and the continued production of milk occur because the breast has developed extensively throughout pregnancy.[29] The ductal system has arborized to form an extended network of collecting ducts. The alveoli are richly lined with epithelial cells varying from flat to low columnar in shape, all capable of producing milk. Some cells protrude into the lumen of the alveoli; others are short and smooth. The lumen of the alveolus is crowded with fine granular material and lipid droplets (Figure 31-3). The division and differentiation of the mammary epithelial cells and presecretory alveolar cells into secretory milk-releasing alveolar cells completes the preparation for milk production. The biosynthesis of milk involves this cellular site, where the metabolic processes occur. There are stem cells and highly differentiated secretory alveolar cells at the terminal ducts. The stem cells are stimulated by growth hormone and insulin, which is synergized by prolactin to stimulate the cells to secretory activity. The breast acts in response to the interactions of the pituitary, thyroid, pancreatic, adrenal,

and ovarian hormones (Figure 31-4).

The process of milk synthesis involves apocrine secretion for the de novo production of fat and protein and the merocrine secretion of lactose

synthesized from glucose.[25] Ions diffuse across the membrane and, in some cases, are actively transported. The primary alveolar milk is then diluted within the lumen to be isotonic with plasma by water that diffuses from extracellular fluid.[28,29] The pathways for milk synthesis and secretion into the mammary alveolus include[28]: (1) exocytosis of protein and lactose; (2) formation of the milk fat globule; (3) secretion of ions and water; (4) pinocytosis-exocytosis of immunoglobulins; and (5) the paracellular pathway (Figure 31-5).

Because lactation is anticipated, the body prepares the breast during pregnancy and also develops additional nutritional maternal stores that will be needed during lactation, in the form of 6–8 pounds of body weight apart from the uterus and its contents. When lactation begins, there is a redistribution of blood supply from the uterus to the breast, where there is an increased demand for nutrients and an increased metabolic rate to accommodate the demands of milk production. The mammary gland may have to produce milk at the expense of other organs if stores are inadequate. There are cardiovascular adjustments as mammary blood flow increases. The mammary blood flow, cardiac output, and milk secretion are suckling dependent. In addition, suckling induces the release of anterior pituitary hormones, prolactin and oxytocin, which act directly on the breast tissue and on the uterus.[28]

In addition to glandular preparation, the nipple and areola are also preparing for lactation. There is an increase in vascularization. The Montgomery glands, which are sebaceous glands on the areolar circling the nipple, become enlarged and begin to secrete a substance that lubricates and protects the areola and nipple during pregnancy and lactation.[16]

The use of ultrasound imagery[30–34] to reexamine the working of the human breast has replaced some beliefs about the anatomy which were originally derived from the dissection of formalin prepared specimens in 1840.[35] Imaging the actively secreting breast has revealed that only about 9–12 (range 4–18) ducts are at the base of the nipple not the original number of 15–25. The duct were measured to be 1.9 ± 0.6 mm (1.0–4.4 mm) in diameter. The number of ducts and their diameter did not correlate with nipple size or radius of the areolar or actual milk production. The amount of glandular tissue in the lactating breast was about 64% (range 45%–83%) of the breast tissue and the fatty tissue only accounted for 38% (16%–51%). There was no correlation between milk production and the amount of glandular tissue as measured by ultrasound.[30,31] The nipple has

many sensory nerve fibers, but the areola does not, an important fact in terms of comfort for the mother while nursing.[32] The response to tactile sensation of the nipple increases dramatically at delivery as an adaptation for lactation that enhances the nervous response to suckling by the infant (Figure 31-6).

INITIATION OF MILK SECRETION

Withdrawal of placental and luteal sex hormones and stimulation of prolactin-releasing factor result in the increased prolactin synthesis by the adenohypophysis, which stimulates milk synthesis in the mammary alveoli. The release of milk from the alveolar collecting ductules depends on the ejection or let-down reflex (Figure 31-6). The let-down reflex is a simple arc that is initiated by the suckling of the infant.[36] This suckling stimulates the mechanoreceptors in the nipple and areola that send stimuli along nerve pathways to the hypothalamus, which stimulates the posterior pituitary to release oxytocin.[37,38] Oxytocin is carried via the bloodstream to the breast and uterus.[39,40] Oxytocin stimulates the myoepithelial cells, which envelop the secretory alveoli and the collecting ductules in the breast, to contract, ejecting milk through the ductule (Figure 31-4) The oxytocin also stimulates the myoepithelial cells in the uterus to contract, causing the “after pains” a mother associates with lactation. Physiologically, this uterine contraction enhances the uterine postpartum involution, so that the uterus of the lactating woman returns to normal more quickly postpartum. Oxytocin release can also be stimulated by seeing or hearing the infant; thus a woman notices that her milk begins to drip when she sees her infant.[40] Prolactin, however, is only released when the breast is stimulated by suckling or pumping.

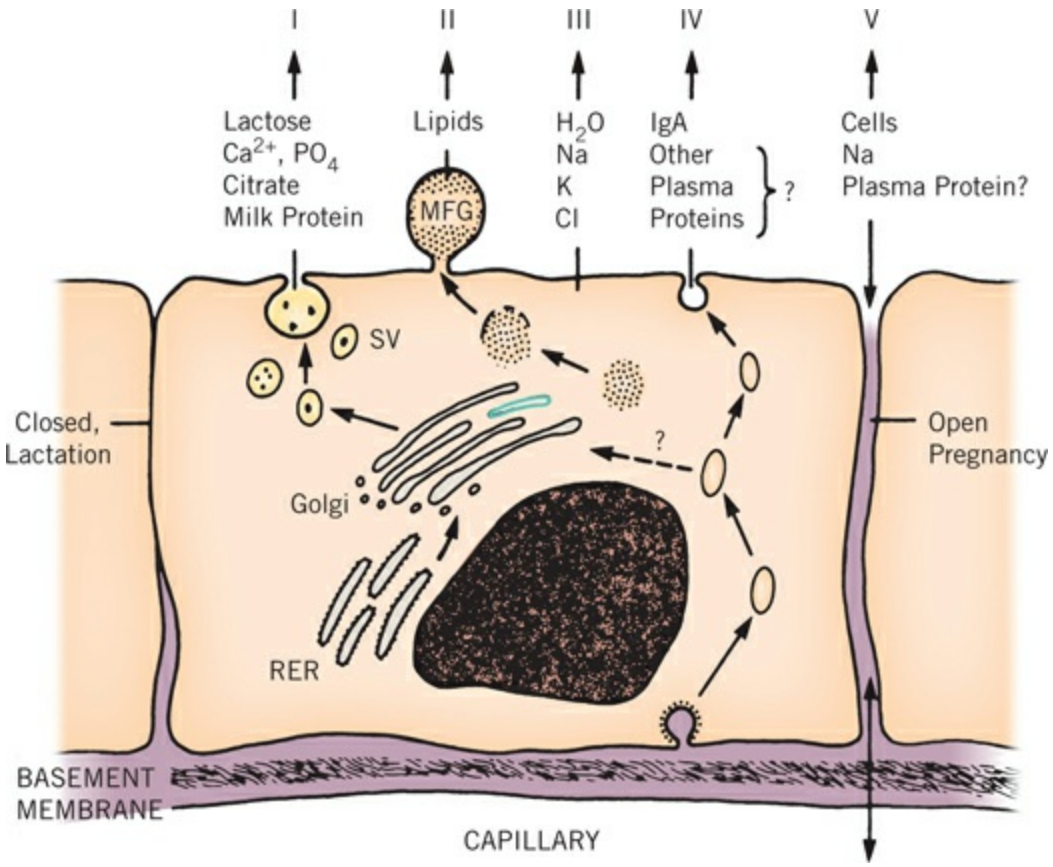

Figure 31-5 The pathways for milk synthesis and secretion in the mammary alveolus. (II) Exocytosis of milk protein and lactose in Golgi-derived secretory vesicles. (III) Secretion of ions and water across the apical membrane. (IV) Pinocytosis-exocytosis of immunoglobulins. (V) The paracellular pathway of plasma components and leukocytes. Figure 31-6 (A) Normal nipple everts with gentle pressure. (B) Inverted or tied nipple inverts with gentle pressure. Reproduced with permission from Lawrence and Lawrence.[10]

Prolactin, which is also released from the hypothalamus during sucking, stimulates the production of milk.[36] Prolactin levels during early lactation are increased 10–20 times greater than normal. The technology required to obtain prolactin levels has been available for clinical investigation, but the role of prolactin in the volume of milk produced is still not clearly defined. It is clear, however, that the surge in prolactin to about twice baseline levels is critical to the successful production of an adequate supply of milk. When evaluating prolactin during lactation, a sample of blood is drawn at baseline and then a second sample is drawn after ten minutes of breastfeeding or pumping with an electric pump.[16] The baseline should be above normal range for the laboratory and post stimulus should be increased to almost double baseline.

PRENATAL CONSIDERATIONS

Although the breast prepares for lactation independent of the mother's

decision to breastfeed, it is important to introduce the question of feeding the infant as soon as possible during pregnancy so that the mother can make an informed choice in behalf of her baby.[37] Although it has been suggested that well-educated mothers have made up their minds about how they will feed their infants long before conception occurs, there are many women who need to be informed about breastfeeding and need to receive reinforcement from their physician.[37] Many women, especially primiparas, will need considerable assistance to lactate successfully. The significant benefits of human milk to the human infant have already been reviewed in previous chapters. The psychological benefits are equally as important to both mother and child.[38]

The nutritional benefits of human milk, although legion, can in part be substituted with a modern prepared formula, but the infection protection, immunologic properties, and the psychological benefits of human milk cannot be duplicated.[21,22] In the mid-twentieth century, when bottle feeding was rampant, the single, clear, unchallenged advantage to breastfeeding that was articulated was the special interrelationship between the mother and her baby.[38] The key elements of attachment are said to include early contact, closeness, eye-to-eye contact, smell, and body warmth. Breastfeeding includes these naturally. A woman has a surge of oxytocin and prolactin during each feeding, which has been demonstrated biologically to stimulate mothering behavior.[39,40]

When a mother wishes to be free of the responsibility of breastfeeding, it is often so that she will not be tied down, will not always have to be available, and can have others feed the infant, thus depriving the infant of this special frequent closeness with the mother.

Preparation of the Breasts

Nature prepares the breasts. It is not necessary to manipulate the breasts and nipples prenatally in preparation in the normal woman. Part of the prenatal physical examination should include the breasts with respect to lactation so that any anatomic variations that may interfere with lactation can be discussed.[37] The size of the breast is not related to lactation success and is not a measure of glandular potential.[34] Women who have had benign cysts removed can still nurse successfully. Augmentation mammoplasty does not usually interfere with lactation if the nipple and duct system have been left intact, that is, the nipple has not been realigned and the implant is placed under the breast tissue on the chest wall. Unless the implant has ruptured and has caused scarring, lactation should be

successful. When breast size has been surgically diminished by reduction mammoplasty, the duct system may have been interrupted if the nipple was completely removed and replaced central to the remaining tissue. This may make lactation improbable, and this issue should be discussed with the operating surgeon. If the procedure was done leaving the nipple and areolar on a pedicle, lactation may be successful. Women who have had one breast removed surgically can successfully breastfeed, although when the mastectomy is for malignant disease, it may not be recommended because of the potential effect of continued high levels of sex steroids in the system if pregnancy occurs within five years of treatment. It should be discussed with the oncologist. Women who are in the process of treatment for breast cancer during lactation may pump and discard their milk for a few days after chemotherapy then resume feeding until the next treatment. Length of time for discarding varies with the drug employed. The time for complete clearance can be calculated as five times the half life of the drug involved.[16] Many of the cancer drugs have very short half lives so the disruption may be less than 24 hours.

Inverted nipples are the most common anatomic problem identified (Figure 31-7). Although there are stretching exercises that can be done to pull the nipple out, exercises require time, considerable dedication, and a commitment on the part of the mother to this daily manipulation. Some mothers find nipple exercises distasteful. Nipple stimulus prenatally may trigger uterine contractions and premature labor especially in the last few weeks. Another method of treatment for inverted nipples is wearing specially designed plastic shells inside the normal brassiere daily during the last six weeks of pregnancy, beginning with a few minutes a day increasing time worn to 8–10 hours after about two weeks. The continued gentle pressure on the areola, stretching the fibrous tissue, will evert the nipple through the central hole. After delivery, these shells can be worn between feedings (but not during) until the eversion is firmly established postpartum and the nipple is easily grasped by the infant. A controlled study by Alexander and colleagues found that the technique was not very effective and it often discouraged some women from even initiating breastfeeding.[41] Inverted or small nipples may best be everted by using a good hand pump or an electric pump just prior to putting the infant in position to latch on for a feeding in the first few days postpartum. Usually, the nipple will remain erect without pumping after a week of these efforts. In subsequent pregnancies, the nipples are more everted probably due to the stretching of the fibers that were tying the nipple down initially.

Figure 31-7 Breast shell in place inside a brassiere to evert the nipple. Reproduced with permission from Lawrence and Lawrence.[10]

Only gentle face soap and clear water are needed for breast care. No ointments or lotions are advised prophylactically as they irritate the skin and plug the natural pores, inhibiting the natural secretions. The sebaceous secretions of the glands of Montgomery on the areola are intended to lubricate the areola and nipple. Buffing the tissues briskly with a turkish towel or a toothbrush is neither necessary nor recommended. In a very dry climate where skin dryness is a problem, a bland ointment such as A and D ointment or purified lanolin might be prescribed in some cases.

Removing colostrum in the last few weeks of pregnancy by manual expression is not recommended as it may irritate the tissues and cause an early mastitis. Because the colostrum is discarded, it wastes a very valuable commodity, which should be left for the infant. Such manipulation of the breast may also stimulate premature contractions of the uterus. Prior to delivery, the mother should purchase and bring to the hospital a well-constructed nursing brassiere to support the breasts, especially as the milk first comes in. This will alleviate the feeling of heaviness and engorgement. Many women wear a nursing brassiere night and day, especially in the first few weeks postpartum.

A new mother may find it helpful to attend breastfeeding classes prenatally and actually see an infant at the breast before she delivers if she is totally unfamiliar with breastfeeding.[42] Many childbirth classes include breastfeeding in the curriculum. If not, the physician may wish to have the office staff provide that educational service or refer the patient to a

community breastfeeding support group, such as La Leche League.

Initiating Lactation: The First Feed

As soon after birth as possible, preferably within the first hour of life, the infant should be breastfed.[10,11] Once the infant is stable, with the airway clear and respirations established, he can be offered the breast with the mother lying on her side facing the infant, who is also lying on his side. The infant should be held close to the breast. The areola will be soft and compressible. If the mother strokes the center of the infant's lower lip with the nipple, he will quickly root, open the mouth wide, grasp the nipple and areola, and begin to suckle. The nipple and areola elongate to form a teat as they are drawn into the mouth. The infant should grasp well beyond the nipple so as to compress the areola and ductules, which lie under the areola (Figures 31-8 and 31-9). Because nipple size and areola size vary, the infant may not be able to get the entire areola into the mouth. Even at the first feeding, the infant will receive colostrum. The mother should be further instructed in the art of positioning herself comfortably and supporting her breast with her hand. Changing her position at different feedings allows the infant to grasp from different angles.[24,42,43] This will rotate the point of greatest suckling pressure and will evenly distribute the suckling pressure over the entire areola. After the first feed, a mother may lie down or sit up as she chooses. If the nipple is tender, the baby can be held on the right breast as if he were nursing on the left side, that is, facing the mother's right side with feet to her right (or the reverse on the left breast, with the infant facing the mother's left side). The key to correct positioning is having the infant face the breast. The infant can be brought close by moving the mother's arm that is holding the infant and not by pushing the infant's head toward the breast. Pushing the head toward the breast causes the infant to arch back away from the breast which is the natural arching reflex. This results when the back of the head is held. This appears to the mother as if the infant is rejecting the breast.

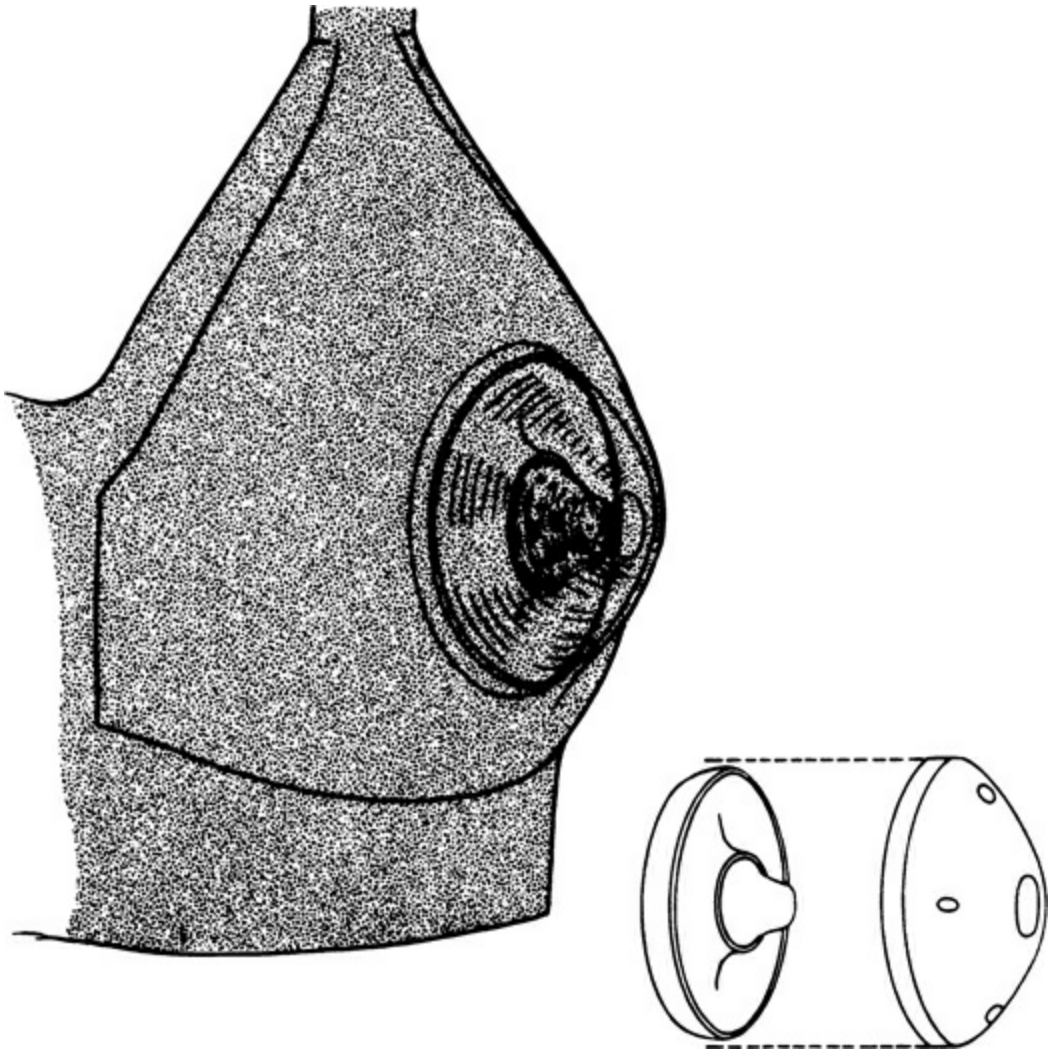

Figure 31-8 (A) As the infant grasps the breast, the tongue moves forward to draw the nipple in. (B) The nipple and the areola move toward the palate as the glottis still permits breathing. (C) The tongue moves along the nipple, pressing it against the hard palate and creating pressure, Ductules under the areola are milked and flow begins as a result of peristaltic movement of the tongue. The glottis closes. Swallow follows. Reproduced with permission from Lawrence and Lawrence.[10]

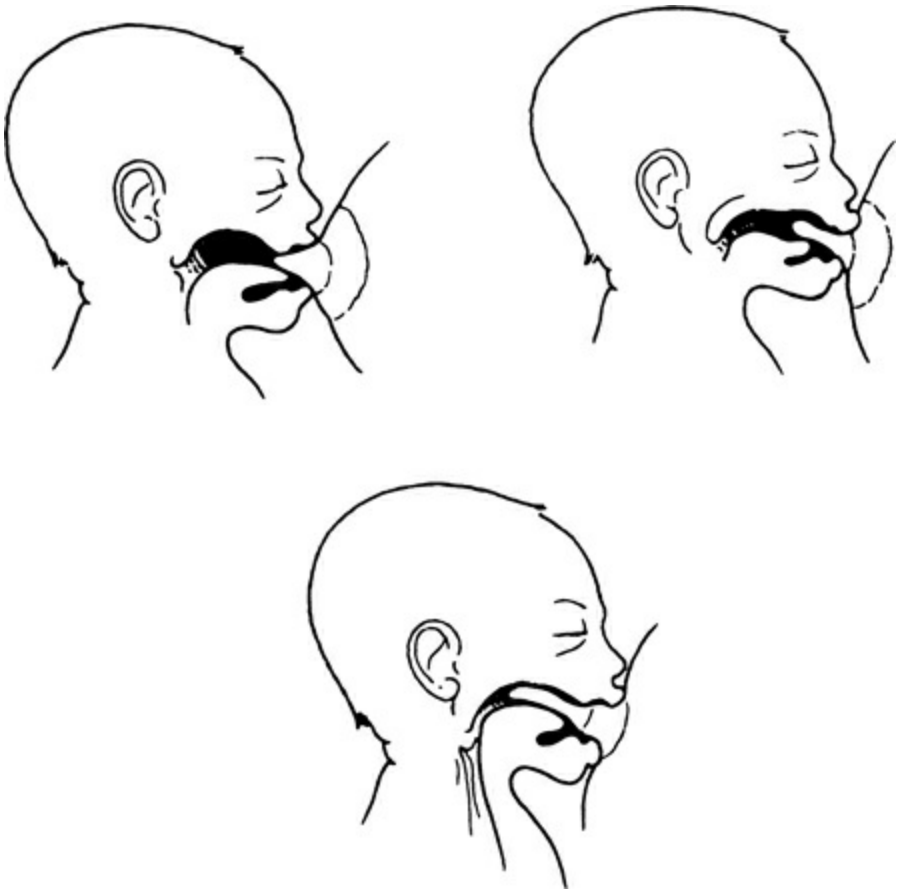

Figure 31-9 Latching on. In response to stimulating the infant's lower lip with the nipple, the mouth opens wide Reproduced with permission from Lawrence and Lawrence.[10]

The position a mother assumes while nursing should be comfortable and relaxing for her. A rocking chair is often the best for the sitting position. It is recommended that a mother may increase her comfort if she varies the hold and orientation of the baby to the breast. This includes not only lying down and sitting up, but holding the baby under the arm in a football hold or across her body so he is held by the left arm at the right breast or the reverse.[16,43,53] The infant should always be facing the breast directly regardless of the position of the rest of the body and the back of the head should not be handled.

Initially, a mother may offer both breasts at each feeding to stimulate each breast as often as possible during the first weeks. The infant, however, should nurse long enough on the first side to receive the hind milk, that is, over five minutes. In reality, he may drift off to sleep before

being switched to the second side. At the next feeding, he should be offered the other breast first. This will balance the stimulus and, thus, milk production. The infant should nurse every time he awakens and is alert and hungry, which may be as frequently as every two hours. Intervals between feedings should not be greater than four to five hours in the beginning when frequent stimulus is critical to establishing a good milk supply. If the infant sleeps six hours, he should be awakened in the first few weeks of life. Having the mother and baby cared for in close proximity as in rooming-in or by mother-baby nursing staff assignments will facilitate frequent appropriate feeding and will enhance milk production. In programs where infants are fed more, on average, 8–12 times a day than six times daily (average 10–12 times), the length of each feeding tends to be shorter. With frequent feeding, there is better milk production, less weight loss, earlier regain of birth weight, and less neonatal jaundice.[44–48] This increase in feeding frequency has not been associated with an increase in sore nipples. Sore nipples are associated with inappropriate positioning at the breast. Care should be taken not to overwhelm the mother with many suggestions for different positions, alternate hand grips, and other angles for the infant. She should find a simple way that works before leaving the hospital. If there is a problem, then different approaches can be suggested. The infant should feed when hungry with no rules for timing or intervals. Crying is a late sign of hunger. Every mother should be observed feeding her baby by a skilled observer before discharge.

Healthy mothers and their infants are being discharged in 48 hours or less in sharp contrast to the —four to five day stay of the past. Mothers with cesarean sections may leave in 36 hours. Having a helpless newborn totally dependent on a mother is an awesome, frightening, and sometimes discouraging responsibility. The mother is no longer an independent person. This responsibility may be overwhelming unless care is taken to “mother the mother” because our culture does not automatically provide maternal support.[49] In fact, our culture programs a superwoman concept in which the new mother must return to her other household chores unless the health professional intervenes. Adequate rest should be prescribed. Discussing the joint responsibilities of parenthood with both parents may facilitate a smoother transition from the sheltered hospital environment to home. Early discharge home also places a responsibility on the physician to see the breastfed infant in the first week of life at home. Provision for weight checks and assessment of jaundice should involve a home visit or an office visit within two days of discharge.[9,47] Many offices have a nurse practitioner skilled in newborn care and breastfeeding who provides this

service.

Nourishment for the lactating woman should make sense, but nurturance while providing these nutrients is equally important. Raphael has expressed it as the need for a *doula*, which is taken from the Greek language to mean "a helpful friend from across the street."[49] It means that someone must care for the mother, support her efforts to breastfeed, and make her confident in her ability to mother her infant.

Supplementation With Milk or Water

Careful study of weight loss in breastfed and formula fed infants in the first days of life indicates that the breastfed baby does not lose more weight than the formula fed baby when breastfeeding is adequately assisted. Furthermore, infants who are fed frequently at the breast in the first few days begin to gain weight at least by the fourth day. Studies correlating the method of feeding with the level of bilirubin show no significant difference between breastfeeding and formula feeding.[46–48] Studies comparing frequency of feeding in the breastfeeding group show that infants who are fed seven or more times per day have significantly lower bilirubins than those fed six or less times per day. Findings were independent of the total number of minutes per day spent nursing.[45,46] In terms of lactation physiology, the breast produces milk in response to suckling and the removal of milk by suckling or pumping. The greatest volume of milk is obtained in the first 5–10 minutes at each breast. If the infant feeds more frequently, he receives more milk, and the breast produces more in response. Animal studies by Gartner and Herschel suggest a relationship between elevated bilirubin levels and starvation.[47] Weight loss of greater than 7% requires evaluation of the breastfeeding, as does unexplained hyperbilirubinemia.[9,44] The increased use of intravenous fluids during labor or with an epidural, has been associated with increased fluid excretion by the infant and greater weight loss. If, on the other hand, the influence of giving water or milk supplements to babies who are breastfed is scrutinized, it is noted that supplementation, especially with water, is associated with increased weight loss and increased bilirubin levels in the first few days of life.[45–47,50] If the influence of water or milk supplements on babies who are breastfed is investigated from the standpoint of successful establishment of lactation, length of breastfeeding, and reasons for early weaning, it is also noted to be negative. Mothers who add supplements have more difficulty establishing a good milk supply, are more apt to wean early, and give "insufficient milk" as a reason for

weaning. Supplements interfere with successful lactation.[51]

In the first few weeks of lactation, it is important to encourage a feeding program that meets the infant's needs, that is, providing feeding when the infant is awake and hungry (the so-called demand or on-request feeding). This may be 12–16 times per day. Most babies have a period of a few hours when they want to nurse every hour and that is appropriate for several feedings. There is, however, a relationship between the fatigue and stamina of the mother that has to be balanced against the true needs of the infant. A fussy breastfed infant who has been well fed may need to be comforted by someone else. This is an important role for the father. Lactating women may not be able to comfort their own infants without offering the breast because the infant smells the milk and will root even though he is well fed. This sometimes leads to incessant non-nutritive suckling, which may be a drain on the mother's energy resources and traumatic to the nipple. Non-nutritive comforting is a significant need of most infants and can be provided by the father.

An additional side effect of supplementation is the use of a bottle and a rubber nipple, which may lead to nipple confusion on the part of the newborn.[52] The sucking mechanism utilized at the breast is the sucking reflex present at birth. The infant will have much of the areola in the mouth, compressing it against the hard palate as it elongates into a teat, maintaining the seal with the gum and lips. The tongue undulates with a peristaltic motion that also triggers the swallow and initiates peristalsis in the esophagus and the stomach. The nipple is a passive passageway for the milk to exit. When a bottle is used, the infant's jaws do little but hold the nipple in place. There is little undulating of the tongue, and milk flows easily with a little suction created by the seal. The tongue may even be thrust upward to control the flow from the unyielding rubber nipple. Because this is a different position and action, some babies are confused by switching back and forth between breast and bottle especially in the first few weeks or when the infant is slightly premature. When the tongue thrusting of bottle feeding is used with the breast, it pushes the human nipple out of the mouth.

Management at Home

Adjustments at home for a new baby are often amplified when the mother is breastfeeding, because any problem such as fussiness, colic, wakefulness, or night feedings are assumed by the mother to be due to a problem with breastfeeding. Instilling confidence in the mother's ability to care for and nourish her infant is important. Closer surveillance by the

physician in the first few days, however, is necessary to be certain that the new inexperienced mother does not interpret long sleeping periods with little feeding as adequate for proper growth. Successful breastfeeding results in fewer problems and illnesses later. Review of weight status, number of wet diapers (at least six per day), stool pattern (at least three per day in the first month), and feeding pattern is a further check on successful lactation. When a breastfed infant does not stop losing weight by five days, does not produce a stool every day, does not void adequately, or does not regain birth weight by 14 days, aggressive intervention is indicated. The physician needs to evaluate infant and the breastfeeding.[53]

Maternal Nutrition

The nursing mother should have a nutrition check to confirm her appropriate food intake. A lactating woman should have 500 extra calories over the pre pregnancy baseline, 20 extra grams of protein, and a balanced diet. Mothers who are concerned about losing weight should be counseled to consume no less than 1800 kcal/day and to consume adequate vitamins and minerals.[8,54] Maternal weight loss after the initial drop should not exceed 1–1.5 kg per month in the first six months of lactation. The most important dietary increase is calcium and phosphorus, to a total of 1200 mg/day.[55] The neonatal calcium-phosphorus requirement exceeds that of the fetus in the last trimester of pregnancy. Dairy products are the best source, but if these products are not tolerated by the mother, she needs to seek out additional sources in dark green vegetables, nuts, legumes, and certain dried fruits. Dark green leafy vegetables such as kale, cabbage, collards, and turnip greens contain readily available calcium, whereas the calcium in spinach, Swiss chard, and beet greens is bound to oxalic acid and is not absorbable.[8,54] The amount of calcium in the diet will not influence the amount in the milk, but a deficiency will lead to leaching from maternal bone and significant osteoporosis. A large placebo controlled study showed that women tolerate 4000 units of vitamin D per day and their milk levels provide sufficient vitamin D to the nursing infant. No supplements are needed for the first six months. Women need to take added vitamin D in pregnancy to provide adequate supplies to the fetus and infant at birth. The current recommendations recommend a daily intake of vitamin D of 400 IU for all infants and children beginning in the first few days of life.[57] A lactating woman does not need added iron for milk but will need to replace stores lost in pregnancy and parturition. A balanced diet should provide all other nutrients. The quality of the milk

day by day is balanced by intake and stores (Figure 31-10). The strict vegetarian is in jeopardy, however, of causing B_{12} deficiency in her offspring, unless she takes supplements, because B_{12} is not found in nature except in animal protein.

Figure 31-10 Energy use in lactation, showing availability of body stores and dietary sources. Reproduced with permission from Lawrence and Lawrence.[10]

TABLE 31-1 Herbal Teas

Ingredient	Botanical Source	Pharmacologic Principle	Use	Effects
African yohimbe bark, yohimbe	*Corynanthe yohimbe*	Yohimbine	Smoke or drink as stimulant	Mild hallucinogen
Catnip	*Nepeta cataria*	Nepetalactone	Smoke or drink as marijuana substitute	Mild hallucinogen
Gordolobo yerbal	*Senecio douglassi*	Pyrrolizidine alkaloids	Drink	veno-occlusive effects, sedation
Hops	*Humulus*	Lupuline	Smoke or drink	sedation,

	lupulus		as sedative and marijuana substitute	diuresis
Kavakava	*Piper methysticum*	Yangonin, pyrones	Smoke or drink as marijuana substitute	Mild hallucinogen
Kola nut	*Cola spp*.	Caffeine, theobromine, kolanin	Smoke, drink, or take as capsules as stimulant	Stimulant
Lobelia	*Lobelia inflate*	Lobeline	Smoke or drink as marijuana substitute	Mild euphoriant
Mandrake	*Mandragora officinarum*	Scopolamine, hyoscyamine	Drink as hallucinogen	Hallucinogen
Mate	*Ilex paraguayensis*	Caffeine	Drink as stimulant	Stimulant
Mormon tea	*Ephedra nevadensis*	Ephedrine	Drink as stimulant	Stimulant
Nutmeg	*Myristica fragrans*	Myristicin	Drink as hallucinogen	Hallucinogen
Passion flower	*Passiflora incarnate*	Harmine alkaloids	Smoke, drink, or take as capsules as marijuana	Mild stimulant
Periwinkle	*Catharanthus roseus*	Indole alkaloids	Smoke or drink as euphoriant	Hallucinogen
Snakeroot	*Rauwolfia serpentine*	Reserpine	Smoke or drink as tobacco substitute	Tranquilizer
Thorn apple	*Datura stramonium*	Atropine, scopolamine	Smoke or drink as tobacco substitute or hallucinogen	Strong hallucinogen
Valerian	*Valeriana officinalis*	Chatinine, velerine alkaloids	Drink or take as capsules as tranquilizer	Tranquilizer
Wormwood	*Artemisia absinthium*	Absinthe	Smoke or drink as relaxant	Narcotic-analgesic

Adapted from AAP Subcommittee on Hyperbilirubinemia.[44] Reproduced with permission from World Health Organization.[10]

The lactating woman does have increased needs for fluids and thus increased thirst. If a woman selects beverages that contain caffeine or other active pharmacologic principles, it could affect the infant. Beverages that either contain no caffeine or have been decaffeinated are appropriate. With the increasing interest in herbal teas, attention should be given to the

content of such teas.[58] A partial list of products is shown in Table 31-1. Many teas contain very potent glucosides which have negative pharmacologic properties; others are benign and a few even nutritious such as rose hips, which contain vitamin C.

Documenting the consumption of herbal teas by the mother or given to the infant directly should be part of the medical history. Some herbs are reputed to enhance lactation such as fenugreek. The required dose is large and soon the milk and all secretions and the infant smell like maple syrup. It helps some women but not all. There can be a cross allergy to peanuts and chickpeas that may cause colic in the infant. Comfrey has been widely used in midwifery and in lactation but is banned in many countries. The FDA has also issued a warning as its use can cause veno-occlusive disease and even be fatal especially in infants.[59]

STAGES OF BREASTFEEDING

Adaptation

Initially, there is a period of adjustment and adaptation as the mother and baby settle into a reciprocal relationship of supply-and-demand. The infant can be exclusively nourished at the breast for the first 6 months of life. During that time, there may be gradual changes in the feeding pattern as the infant matures and sleeps longer between feedings and also spends more time awake and socializing. Growth spurts are accompanied by a temporary increase in feeding frequency. This may alarm the mother if she has not been alerted to this possibility. Periods of stress or illness in the infant may be marked with temporarily increased suckling, especially non-nutritive suckling for comfort. Human milk meets all the nutrient needs of the infant for the first 6 months except for a select group of women who live in cold climates with little sunshine, have dark pigmented skin, wear occlusive clothing or use sunscreen frequently who may be vitamin D deficient.[56,60] Concern about widespread vitamin D deficiency has resulted in reconsideration of vitamin D requirements. Recommendations from the Center for Disease Control and Prevention suggest supplementing the infants with 400 units vitamin D daily by mouth with vitamin D only preparation for breastfed infants. [57] They should be supplemented as mentioned. Very low-birth-weight infants may need iron. Healthy exclusively breastfed infants do not need iron for the first 6 months of life. When weaning foods are added in the second 6 months, they should be iron containing such as iron supplemented cereal.[62]

Adding Solid Foods

The infant ideally is exclusively breastfed for the first 6 months. The single nutrient needed to add to solid foods in an exclusively breastfed infant is the need for additional dietary iron, thus introduction of iron fortified weaning foods at around 6 months is recommended, although the exact age is poorly defined.[62] At about 6 months of age it is appropriate to begin the addition of solid foods to the infant's diet for nutritional reasons.[62] Learning to take solid foods is also an important developmental milestone that involves a new use of tongue, jaw, and lips—a use that differs from suckling.[63] Beginning to take fluids from a cup is also a developmental task that should be learned around 7 months of age. The infant who is exclusively breastfed to this point needs to explore these activities and develop these skills just as a bottle fed infant would. The fluids can be water, juice, or pumped breast milk. If a mother continues to provide her milk, there is no need to introduce formula. Cow's milk when the infant is younger than 1 year of age is not recommended.

Weaning

To wean is "to transfer the young of any animal from dependence on its mother's milk to another form of nourishment" or "to estrange from former habits or associations" according to the dictionary.[63] The weaning process takes many forms, depending on the mother's schedule and beliefs and the needs of the infant. Some women plan to breastfeed for only a few months "to give the baby a good start"; other mothers wean as soon as solid foods can be started, and some continue to offer the breast for several years, even during a subsequent pregnancy and while feeding a new baby. The appropriate time for weaning should be based on nutritional and psychological needs and developmental milestones. Feeding is an important social as well as nutritional encounter, and eating solids and drinking from a cup are important social accomplishments. This does not mean the infant is taken completely off the breast. In practice, the mother is usually the instigator of weaning. The process ideally is gradual, replacing one feeding at a time with solids and the introduction of a bottle or cup, depending on the infant's age and stage of development. After the adjustment has been made to substitute one feeding, a second feeding is replaced, usually at the opposite time of day. The process is continued until there is only one nursing at night and one in the morning. These two feedings may be maintained for many months or gradually discontinued over weeks. A mother may be able to express milk from the breast for

weeks after the final feeding. An infant who has not weaned by 18–24 months usually does not spontaneously wean until 4–5 years of age.[16]

Emergency weaning because of a crisis such as illness or separation may be stormy for the dyad. The infant may reject the bottle and refuse all nourishment at first. The mother who abruptly weans may experience severe engorgement, pain, and systemic symptoms attributed to the resorption of milk and referred to as “milk fever”. Emergency weaning is facilitated by the assistance of another adult who can initiate the new feeding method and is patient and understanding with the child. Cup feeding with a small medicine cup may be a helpful alternative. In the face of recent natural disasters, the importance of keeping mothers and infants together and supporting breastfeeding as an acceptable, feasible, affordable, safe, and sustainable (AFASS) manner of continuing to provide adequate nutrition to the infant has been reemphasized.[64]

Breastfeeding and the Return to Work

Returning to work has been cited by epidemiologists as a major hurdle in the initiation and duration of breastfeeding.[65,66] Women who need to return to work or to school, often think it is best not to start breastfeeding. Before the industrial revolution, all women worked on the farm or in a cottage industry keeping their children with them. In developing countries today, women carry their infants with them to feed them whenever necessary while working. It was the industrial revolution that separated home and work and made parenting a separate role for women.

More women are employed today outside the home than ever before.[67] Women with children under 6 years of age are the fastest growing segment of the female work force in 2010 (64.2% of women with a child under 6 years old).[68] Even more startling are the number of working mothers with children younger than 3 years of age (61.1%).[68] Of the women who work during pregnancy, over 50% plan to return to work by three months postpartum. These dramatic statistics make it clear that the decision about infant feeding is an important part of this issue.[69,70] Child care also presents another consideration for the women who may well have to choose day care or some form of child care that means her infant will be in close contact with other children. In modern pediatrics, “Day Care Syndrome” is real. It is the increase in number of infections, especially diarrhea, respiratory illness, and otitis media experienced by young infants in day care.

The data are clear that breastfeeding impacts these figures. A

quantitative study has shown that extending breastfeeding from 4 months of age to 6 months decreases the risk of respiratory infection including pneumonia and otitis media even further.[19] The protective properties in human milk (Chapter 30) are even more important for the child exposed to other children early in life while mother works or attends school. A comparison of mothers absenteeism showed that those who were breastfeeding had reduced absenteeism.[69] Looking at illness rates of children whose mothers work, 75% of children who were bottle fed were ill and only 25% of those breastfed had any illness.

The feeding pattern for mothers who work: Ideally, the mother does not return to work for at least 6 weeks so she is able to establish her milk supply before having to add work to her schedule. Mother will have to decide how she will cope.[71] If her job permits her to visit her child several times a day, then she can just feed the infant at the usual times. An employer who has a day care center on the premises makes such an arrangement possible. Professional women who control their own schedules (lawyers, doctors, consultants) may be able to keep the infant on the premises under the care of a baby attendant and feed on demand. For most women, however, their jobs are more rigid and they may have to settle for an opportunity to pump their milk every three or four hours on lunch or coffee breaks and store the milk in a cooler to take home for the next day's feedings. Most women practice pumping at home several weeks ahead of time and store up a supply of milk in the freezer so they do not run out.

Employers such as hospitals, health departments, and family friendly industries like Amoco Chicago, Dow Chemical of Midland, Michigan, and the Los Angeles Department of Water and Power to name a few, have been recognized for their support of "Healthy Mothers and Healthy Babies" and their accommodations for nursing mothers. They provide a room to pump, electric pumps, refrigerators, and in some cases lactation consultants to assist with any breastfeeding issues. This support improves the incidence and duration of breastfeeding for the working woman.[71]

Pumping and Storing Milk

If the employer does not provide pumps, a mother should obtain a pump by either renting or purchasing several weeks in advance of the return to work. All pumps are not equal.[72,73] There are, however, several brands of good portable electric pumps that provide disposable attachments for those parts that contact the breast and the milk. Attachments that allow pumping

both sides simultaneously save time and for some women stimulate more milk release. Other women find double pumping overwhelming and choose to do one side at a time. Hand (manual) pumps are good for stimulating milk release and relieving engorgement but not for large volume pumping for most women. Many hospitals have lactation consultants on staff and a shop or service that rents pumps and sells other breastfeeding devices such as breast pads and storage bottles. Information about local resources should be available on the postpartum floor. If not, a mother can call La Leche League International, 1-800-LALECHE (1-800-525–3243) for a local contact person. After each pumping session, the disposable flanges, tubing and bottles used for pumping should be rinsed with cool water first and then washed in warm soapy water and thoroughly rinsed and air dried. After rinsing with cold water to remove the milk, the equipment may also be washed in an electric dish washer.

The pumped milk should be placed in a glass bottle or a firm plastic polypropylene nursing bottle that can be capped with an airtight seal without a nipple, and then used to feed the infant later. Polyethylene bags are adequate for term baby use. Storage temperatures and times have been carefully studied.[72] The container which should be labeled with name, date, and time should be placed in a refrigerator immediately or in a cooling bag or container with freezer packs if at work or school where there is no refrigerator. It is safe in a cooler bag as long as the packs remain cold (24 hours). Upon arrival home, the bottles should be placed in the refrigerator if it will be used within three days or in the freezer if stored for later use. When milk is pumped at home, milk can be placed in the refrigerator (4 degrees C) immediately and kept for five days. Actually, when there is no alternative or a bottle has been inadvertently left out, milk can be kept in a sterile container at room temperature for eight hours and then used immediately or refrigerated for a day.[16]

If milk is placed in the freezer of the refrigerator that has a separate door, it can be stored for three months if it is placed in the back to avoid thawing and freezing when the door is opened. If milk is placed in a deep freeze (−20°C), it can be kept for 6 months or if at –70°C, it is good for a year or longer.[67,72–74] The impact of freezing on the milk is minimal, destroying only the cells and their function. The effect of refrigeration is also minimal, decreasing the cells and some of their function. Nutrients are unchanged. Storing mother’s milk for her own infant does not require pasteurization. Providing donor milk to another infant does require pasteurization by regulation due to the increase in risk of infection in the present environment. Pasteurization does affect some properties destroying

cells and decreasing lipase activity and some other enzymes (see Table 31-2).[67,74]

Day Care for the Breastfeeding Infant

In choosing a day care service, care should be taken to assure that breastfeeding and breast milk are welcome. When taking an infant to day care, a mother may wish to nurse the infant just before she leaves her child or she may wish to nurse the infant at day care when she has a break from work. Further, she may wish to feed the child before she sets out for home with the infant in the afternoon. There needs to be a place to sit quietly with the infant out of the mainstream of activity. The staff should be prepared to make these accommodations and delay a feeding if mother is going to arrive shortly.

TABLE 31-2 Storage and Use of Pumped Milk for Healthy Term Infants

Place	Length of Time
Refrigerator (4°C)	5 d at home; 3 d in day care
Freezer section (separate door) refrigerator (−20°C)	3 mo
Deep freeze (manual defrost) (−20°C)	6 mo
Commercial deep freeze (−70°C)	1 y
Sterile container @room temperature (23°C) (not ideal but milk need not be discarded)	8 h
Stored in cooler bag with frozen packs (as long as packs are still cold)	Less than 24 h
Thawed previously frozen in refrigerator	24 h

The mother will probably wish to provide her stored breast milk for her infant to receive during the day. It is not necessary for the caretaker to wear gloves to handle the milk or feed the infant. It is, however, appropriate to wear gloves to change any babies' diaper. If the milk was frozen, it can be thawed in the refrigerator at day care or thawed by swirling in a container of warm water. It should not be warmed in the microwave because of possible hot spots and scalding the infant. Microwaving interferes with the anti-infective properties as well as decreasing the vitamin C content. If the infant does not empty the container, it can be refrigerated and fed later unless it has been microwaved.[16] This is not true of formula but the protective factors in

human milk will keep the bacterial count down. The day care attendants should save the containers for reuse by the mother. Thawed breast milk can be maintained in the refrigerator for 24 hours.

The milk containers should be carefully labeled with name and date of collection. The attendant should carefully confirm the name on the container before feeding. Mishaps of giving the wrong milk to the wrong infant do occur. It should be reported to both families and the day care's medical consultant with an incident report. There are no reported cases of injury following such an event.

FAILURE TO THRIVE WHILE BREASTFEEDING

Paralleling the increasing incidence of breastfeeding, there has been an increase in the number of clinical reports, including one in the *Wall Street Journal* and one in the *New York Times*, each describing a few cases of failure to thrive while breastfeeding.[50,75–78] The *New York Times* followed the dramatic story of a teenage mother prosecuted for the death of her eight–week-old breastfed son from starvation. The event followed a series of misadventures and refusal to see the child at a Medicaid clinic.[78] The majority of these cases have reflected a lack of clinical knowledge on the part of the professionals regarding the basic physiology of lactation[77] and a general failure of the health care system to provide an appropriate safety net for new and inexperienced mothers following the current early postpartum discharge practices (hospital stay ≤ two days). As cost drives the healthcare system to earlier and earlier discharge, the risk of infant problems increases since lactation will not be well established prior to discharge.[79,80] The American Academy of Pediatrics has recommended that infants be seen by the pediatrician within a week of discharge but in two days if breastfed.[9]

Failure to thrive in children has been thoroughly reviewed in Chapter 47; however, there are some critical differential factors when the infant is breastfed. Most cases of significant failure to thrive in the breastfed infant manifest themselves in the first few weeks or months of life. There is also an important distinction between failure to thrive and the slow gaining breastfed infant.[51,77] The weight curve of an adequately nourished breastfed infant from birth may well include a weight loss of 6%–8% and the regain of birth weight at 10–14 days in contrast to the formula fed infant who may lose only 3%–4% of birth weight and quickly regain birth weight by 5 to 7 days often beginning on a path to obesity.

The critical clinical distinctions between failure to thrive and slow gaining are enumerated in Table 31-3. The salient points include the slow increase in weight compared to the erratic gaining and losing pattern in failure to thrive. The slow-gaining infant is alert and active, with good skin turgor and muscle tone. He feeds frequently night and day, wets many diapers with pale dilute urine, and has a normal stool pattern. The infant looks scrawny but well.[77]

When the infant who is failing to thrive sleeps long periods between feeds; the lack of feeding may be mistakenly considered satisfied when actually he has starvation inanition. The infant often fed poorly in the first few days or for various other reasons does not stimulate good milk production. Since breast milk production depends on supply-and-demand phenomenon, when the infant sucks weakly, he receives little milk, and thus remains weak from some degree of starvation. This infant also has few wet diapers, the urine is concentrated and described as “strong” by the mother. There are few and small stools, often the green mucus of starvation. The tone and turgor are poor, the cry is weak and infrequent, and the infant looks sick. This may well be a medical emergency requiring hospitalization. The feeding pattern should be evaluated, especially focusing on the length of time spent at the first breast during a feeding to be sure it is long enough to allow the high-fat hind milk to be obtained. Sometimes the pattern of slow gaining can be reversed by limiting a feeding to a single breast to ensure high-fat, high-calorie feeds.[81] Switching back and forth between breasts several times during a feeding do not increase milk supply and can reduce the amount of high calorie fat provided to the infant.[77,81]

The diagnostic work-up of these phenomena requires the same clinical assessment that is appropriate when the infant is not breastfed and for this, the reader is referred to Chapter 47 (Failure to Thrive). Since the breastfeeding infant is part of a synchronous dyad, there are additional considerations in the differential diagnosis.[16] A suggested schema for identifying the cause of the problem is presented in Figure 31-11. The clinician should take a history oriented to the process of lactation. This history should include additional parameters that affect the success of the breastfeeding dyad, such as the mother’s perinatal history, general health, diet, habits, psychosocial state, social support system, and the attitudes of the father and family about breastfeeding. Parameters unique to the breastfed infant include any anatomic or physiologic conditions that would interfere with sucking, which is a critical link in the milk production process.

Difficulties with sucking include anatomic abnormalities that result in mechanical interference with sucking such as cleft lip, cleft palate, hypoplasia of the jaw, macroglossia, ankyloglossia (tongue "tie") and tumors or cysts of the oropharynx. These abnormalities can be identified by physical examination, which includes observation of the infant's suck. There may be neurologic interference resulting in a diminished or absent suck. Events at birth, such as maternal anesthesia or analgesia and fetal anoxia or hypoxia, may contribute to poor suckling in the immediate neonatal period and failure to provide adequate stimulus to the breast to initiate lactation. The ensuing lack of nutrition for the infant leads to hypometabolism and continued lack of vigor. Congenital cardiac anomalies may present in this manner. Other causes of neurologic deficit in sucking include trisomy 13–15, trisomy 21, and neuromuscular syndromes such as Werdnig-Hoffmann, neonatal myasthenia gravis, and congenital muscular dystrophy. Hypothyroidism, prematurity, and congenital intrauterine viral infections contribute to poor suck and lack of vigor. The greatest number of infants, however, are entirely normal but have not had sufficient assistance in establishing the proper grasp of the breast, and possibly have been further confused by being given a bottle supplement, which continues to confound their learning experience.[52] In addition to examining the infant and the maternal breast, the clinician should observe the feeding dynamics.[79,80]

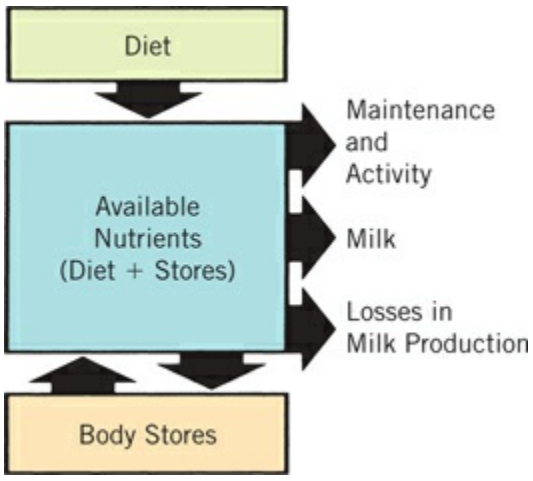

Figure 31-11 Diagnostic flow chart for failure to thrive. Reproduced with permission from Lawrence and Lawrence.[10] CNS, central nervous system; SGA, small for gestational age.

TABLE 31-3 Differential Diagnosis in Poor Weight Gain	
Slow Gainer	Failure to Thrive
Alert, healthy appearance	Apathetic or crying
Good muscle tone	Poor tone
Good skin turgor	Poor turgor
At least six wet diapers daily	Few wet diapers
Pale unconcentrated urine	“Strong” urine
Stools frequent and seedy (or, if infrequent, large and soft)	Stools infrequent and scanty
8 or more nursings daily lasting 15–20 min	Fewer than 8 feedings, often brief
Well-established let-down reflex	No signs of functioning let-down reflex
Weight gain consistent but slow	Weight erratic (loss may occur)

Reproduced with permission from World Health Organization.[10]

All physicians who counsel breastfeeding mothers should be knowledgeable about normal sucking at the breast so that observation of lactation in a diagnostic situation can be constructive. The style with which the mother approaches a feeding, her body language, may be a clue. If she is relaxed, confident, loving, and gentle with her infant, it suggests it is not maternal inexperience at fault. Her verbal interaction can be revealing. A baby suckling at the breast brings reflexive eye-to-eye contact, stroking, and verbal nuances that a seasoned lactating woman utters without consideration for the environment. The insecure, inexperienced mother will sit tensely, offering the breast gingerly, with little or no verbal communication to the infant. If the process is mechanical or punctuated by unrealistic commands to the infant, it may suggest an inability to help the infant root, grasp, and suckle properly. Rigidly timed feedings that are scheduled by the clock may result in poor milk production. The treatment rests with frequent on-request feedings that fit the infant’s biologic rhythms. Suggesting a quiet room, a rocking chair, soft music, or a relaxing beverage for the mother may all improve the situation.

The behavior of the infant when offered the breast may indicate an infant with a suckling disorder, not associated with any other neurologic symptom or long-range problem. Sucking inadequately at the breast can be altered so the infant learns the technique. The infant is identified when it is noted the infant cannot maintain the breast in the mouth unless his mother holds it there. In other words, when she takes her hand away, the breast

falls away. A normal infant sucks without help from his mother's hands if the grip is proper and the seal is adequate. When the infant does begin to suck when the breast is held in position, the suck may be a flutter or ineffective tongue actions. This may be improved by having the mother hold the breast between thumb and index finger, with fingers under the breast (palmar hold) (Figure 31-12) rather than with areolar compressed between the middle and index finger (scissor hold) (Figure 31-13). The infant's position should be adjusted so his body is turned toward the mother's body (instead of just turning his head). Thus, the breast is centered toward the infant, and this position will improve the effectiveness of the infant's efforts. The mother may have to continue to hold the breast in place for weeks until the infant perfects his technique. The mother may also have to pull his lower lip down to keep the infant from drawing the lip into the mouth and moving it along the lower surface of the breast. The lip should be held as part of the seal holding the breast in place and permitting development of some negative sucking pressure. If the mother stimulates the rooting reflex by stroking the center of the lower lip, the infant will open wide and draw the nipple and areola into the mouth to form a teat.

While the infant is learning to suckle properly, it is urgent to avoid introduction of a rubber nipple on a bottle or a pacifier.[52,79,80] This poses a problem if adequate nutrition is critical and the mother's supply needs to be stimulated to be adequate. A trial of frequent feeds, waking the infant every two hours, may suffice. Extra calories may be offered by medicine cup or Haberman feeder. When the failure to thrive has reached critical starvation, a more aggressive approach is mandatory. If hospitalization is necessary, intravenous therapy to treat dehydration may also be necessary. Hypernatremia and hypochloremia have been described, and a complete work-up including pH, electrolytes, BUN, and creatinine are essential.[29,50,53,82,83] While the infant receives intravenous therapy, the mother should be assisted to pump frequently to develop and increase her milk supply. When it is safe to begin oral feedings, the infant should be exclusively breastfed as far as sucking is concerned, and additional nourishment should be provided by intravenous line, gastric tube, or medicine cup. Thus, the infant avoids the introduction of a bottle. When the crisis has abated and full breastfeeding is appropriate, but the milk production is still inadequate, the use of a nursing supplementer (Lact-Aid) may be useful. This device permits the uninterrupted nursing at the breast while supplementary nourishment is provided via a fine capillary tube that runs along the breast into the infant's mouth (Figures 31-14 and 31-15). The tube brings the supplementary fluid from a reservoir plastic bag that

hangs around the mother's neck. The system is carefully engineered. It provides fluid only when the baby sucks; thus, it coordinates with the infant's swallowing mechanism. It is not a siphon or a pump. When used to help establish or increase milk production as with a premature infant first going to breast, the infant is usually weaned from the supplementer within one or two weeks by providing smaller and smaller volumes of supplement as maternal production increases. The supplementing device may make the critical difference when the degree of starvation is great and lactation is being preserved. It is important to point out that all too often the infant is quickly weaned to a bottle without any effort to solve the underlying lactation problem, which is unfortunate (Figures 31-14 and 31-15).

In rare cases of failure to thrive while breastfeeding, the underlying cause is actually metabolic and the infant does even less well on formula prepared from cow's milk or soy protein. In that case, it is quite possible to have the mother re-lactate. It is an art practiced in most cultures over the centuries and resorted to when the biologic mother became ill or died and another female (often the grandmother) had to assume the nourishment of the baby. In the case of premature weaning, there has already been the biologic stimulus of pregnancy and early lactation so reinstituting the milk supply occurs more easily. The lactation supplementer may be of great value in this situation, as the infant can return to the breast and be nourished with donor human milk while the mother builds up her own supply (see Figure 31-15).

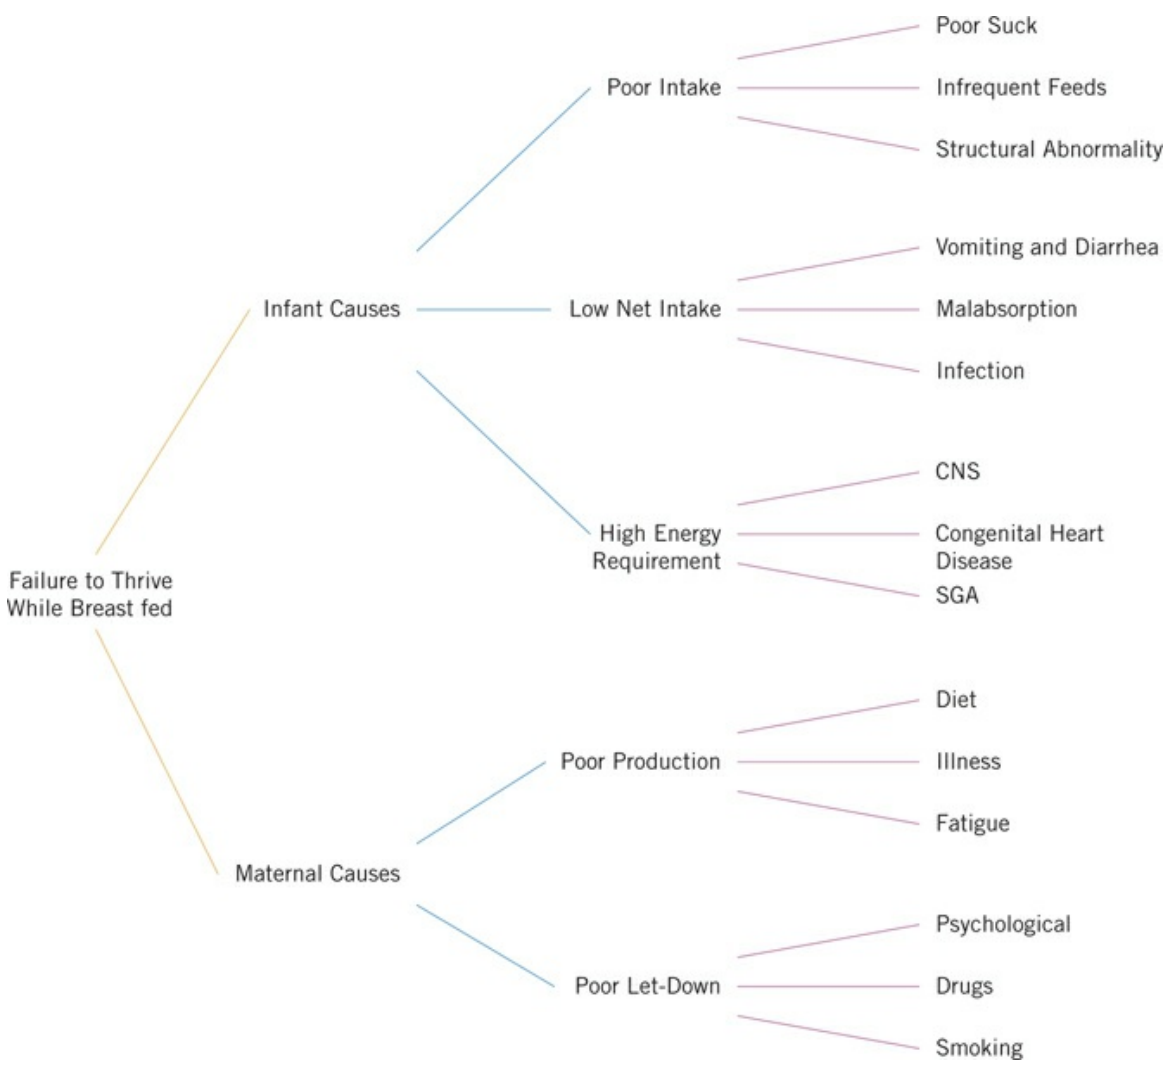

Figure 31-12 Palmar grasp (C-hold). When the palm and fingers cup the breast with support and the thumb rests lightly above the areola, the nipple projects straight ahead or slightly downward (correct). Reproduced with permission from Lawrence and Lawrence.[10]

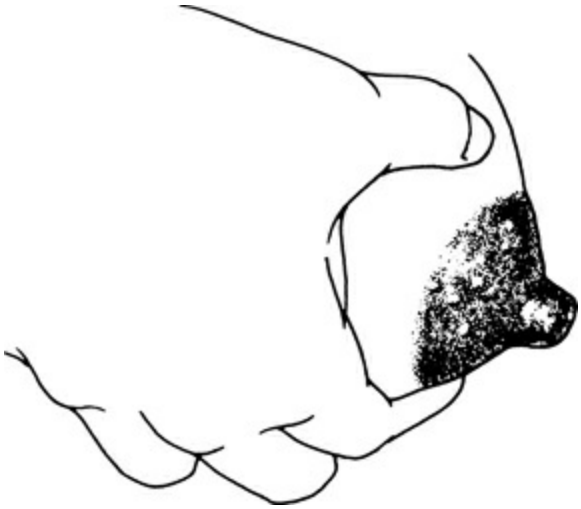

Figure 31-13 When the breast is offered to the infant, the areola is gently compressed between two fingers and the breast supported to ensure that the infant is able to grasp the areola adequately. Reproduced with permission from Lawrence and Lawrence.[10]

Maternal Causes of Failure to Thrive

Poor milk production may be the cause of the failure. This is usually characterized by an alert, active infant who cries hungrily and is very demanding but never satisfied. This baby demands attention and is usually

seen by the physician because of his dissatisfaction. The quiet, sleepy, starved baby gets into serious trouble before he is discovered because his sleeping is interpreted as satiation. It is rare in the United States that diet is the true cause of insufficient milk although it is appropriate to evaluate the mother's diet and make recommendations for increases or adjustments where needed (see Figure 31-11).[84] An additional 600 kcal or a minimum of 1800 kcal/d, a balance of foods with 20 gm extra protein and 400 mg extra calcium, is minimal for every mother. Many mothers feel better taking Brewer's yeast. "Mothering the mother" by caring about her diet may have a positive effect. However, the major factor in poor production is fatigue. It is the single most important element in milk production. The present day "super-mom" model that has been developed by women may be the actual destructive element. A postpartum woman needs rest to recover whether she nurses or not. When she is also nourishing an infant she needs more rest. This is often neglected when the infant needs care every three to four hours around the clock, and only the mother is involved in the feeding of the infant. When her physician suggests that the mother needs to reorder her priorities and schedule naps for herself, it may be the necessary official approval she needs to do so. A mother may need to be told it is not only okay but it is necessary for her to take care of herself in order to provide for her baby. The physician may need to prescribe rest as well as nourishment.

There is a small number of women who are unable to make sufficient milk. Some of these women have inadequate glandular tissue. Markedly asymmetric breasts, conical-shaped breasts, and extremely small ones may be in this category. Even extremely large breasts are occasionally nonfunctional. Failure of the breasts to change and enlarge during pregnancy and/or failure of the breasts to become engorged immediately postpartum are signs of inadequately functioning tissue. These signs prenatally should alert the medical team to extra vigilance as lactation is initiated.

Failure to Let Down Milk

A woman may make milk abundantly but be unable to release it. As the practitioner observes the lactation process, evidence of successful let down should be sought. If the sucking is interrupted by breaking the suction (by putting a finger in the corner of the infant's mouth), milk should continue to flow in a steady drip if not a stream. Although many women describe a tingling, and turgescence when the milk lets down; it is possible to have an effective ejection reflex without these sensations. As indicated in Figure

31-16, it is possible for pain or stress to interfere with let down. If mother has sore nipples or the infant has an improper grasp at the breast, the pain may interfere with let down.[36,16] If the adjustments and remedial actions to avoid stress and enhance confidence do not result in a change in the release of milk, it may be necessary to temporarily provide the oxytocin needed for the let-down arc.[16] Synthetic oxytocin can be prepared by the pharmacist as a nasal spray for home use utilizing the injectable oxytocin. It is packaged in a 5–10 mL nasal dropper bottles. It contains 10 USP units (IU) per milliliter of oxytocin, a polypeptide hormone of the posterior pituitary gland. A prescription is required. It is destroyed in the gastrointestinal tract; therefore, it must be used nasally on the mucous membranes where it is rapidly absorbed. Four to six drops into one nostril followed by having the infant suckle within twoto three minutes is sufficient. This is repeated using the second nares if the infant is switched to the second breast. This may also be used when using a breast pump and collecting for an infant who cannot nurse directly as in the case of a premature baby. Usually, it is only necessary to use the medication for a few days as the natural process will take over.

A rare finding in lactation failure is the lack of a prolactin surge when the breast is stimulated by the suckling or pumping. The prolactin should double over baseline upon suckling. If prolactin levels are obtained, the samples should be carefully timed so that the baseline sample is drawn from a heparin lock after the mother has recovered from the needle stick. Then she should feed the infant or pump her breasts for 10 minutes, and a second sample should be drawn. The percentage increase in prolactin over baseline should approach 50%. The baseline should be above normal for the laboratory. Replacement prolactin is not clinically available although prolactin stimulation with fenugreek or meclopromide or other galactogues may increase milk supply while the treatment is continued.[16]

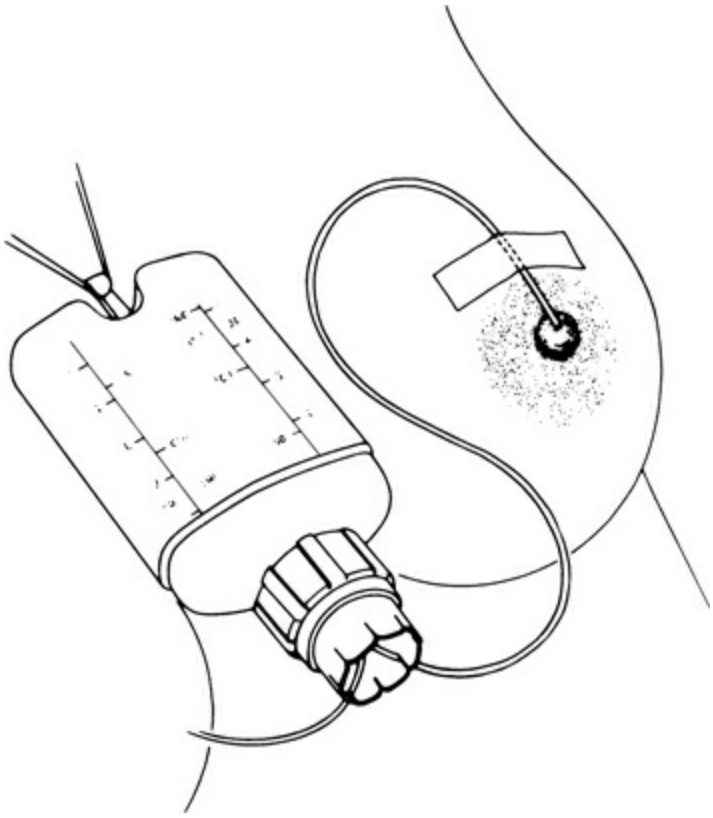

Figure 31-16 Ejection reflex are. When suckling the breast, the infant stimulates mechanoreceptors in the nipple and areola that send a stimulus along nerve pathways to the hypothalamus, which stimulates the posterior pituitary to release oxytocin. It is carried via the bloodstream to the breast and uterus. Oxytocin stimulates myoepithelial cells in the breast to contract and eject milk from the alveolus. It is secreted by the anterior pituitary gland in response to suckling. Stress such as pain and anxiety can inhibit the let-down reflex. The sight or cry of an infant can stimulate it. Reproduced with permission from Lawrence and Lawrence.[10]

Knowing When to Discontinue Breastfeeding

Although breastfeeding provides species-specific nourishment, infection protection, immunologic protection, and psychological benefits for both mother and baby, there are times when it should be discontinued. The role of the physician is a delicate one, one in which true support of breastfeeding is necessary for credibility. On the other hand, the physician must recognize when other alternatives are medically preferable. The mother will need help in accepting this. Having to wean prematurely or

before the planned date is not to be construed as maternal failure. It is still possible to nurture the infant, to be a good mother, and to have a good mother–infant relationship, even though the mother may no longer be able to breastfeed.

The indications for premature weaning are rare but include severe illness in the mother, severe galactosemia in the infant, and a few maternal drugs such as therapeutic doses of radioactive pharmaceuticals.[16,85] An important resource for all healthcare professionals related to drugs and lactation is LactMed, Drugs, and Lactation Database maintained by the National Library of Medicine.[86] Useful resources which healthcare professionals can share with mothers and families are The Nursing Mother's Companion and the New Mother's Guide to Breastfeeding.[87,88]

The Low-Birthweight Infant: Inpatient Care

32

Thibault Senterre, MD, PhD, FRCPC and Alexandre Lapillonne, MD, PhD

INTRODUCTION

The major objective when caring for low-birth-weight (LBW, <2500g) infants is to allow them to grow and develop adequately. In industrialized countries, most LBW infants who are admitted in neonatal units are small because of prematurity. In contrast, and especially in resource-poor countries, some LBW infants are born at term but have suffered from intrauterine growth restriction (IUGR). Their duration of hospitalization is usually short and their nutritional support is similar in practice from that of moderately preterm infants. Therefore, specific inpatient care of term LBW infants with IUGR falls out of the scope of this chapter that focuses on preterm infants.

Recent advances in perinatal medicine and in neonatal intensive care have dramatically increased the survival of preterm infants, especially that of very low–birth-weight (VLBW, <1500g) and extremely low-birth-weight (ELBW, <1000g) infants. Unfortunately, most of these infants develop an extrauterine growth restriction (EUGR) due to inadequate or insufficient nutritional intakes. Nowadays, this problem has emerged as a frequent co-morbidity that is associated with poorer short but also long-term outcomes.[1–3]

Nutritional requirements for preterm infants need to consider: (1) fetal growth according to gestational age (GA), focusing on lean body mass

growth and accretion of proteins, minerals, and various essential nutrients during the last trimester of gestation; (2) the risk of cumulative nutrient deficit acquired during the first weeks of life; (3) the opportunity for early catch-up growth resulting from IUGR; (4) the use of a relatively immature gastrointestinal tract to provide nutrition; and (5) the need to adapt the recommendations in relation to GA.

This chapter aims to highlight the current knowledge on the nutritional requirements of preterm infants and to emphasize on how to optimize practices by using either the enteral and parenteral route in order to reduce the incidence of EUGR and to promote optimal health of very preterm infants.

INPATIENT GROWTH

The Fetus as the Reference for Growth

Optimal growth is generally defined by the growth that is expected to be observed with optimal nutritional intakes and adequate environment. It varies in each individual according to genetic potential and health status. For the preterm infants, the objective generally admitted is to have a growth similar to that of the fetus up to the due date and similar to that of the breastfed term infant afterward.[4–6] Even if this concept is accepted by most neonatologists all around the world, it remains imperfect because many differences exist between the intrauterine fetus and the extrauterine growing preterm infant, particularly for energy expenditure, metabolic demand, and route of nutrient delivery. Fetal growth rate is extremely high during the third trimester of gestation and is much greater than during any other periods of life. If the mean fetal weight gain during the last trimester of gestation is ~15 g/kg/d, it should be emphasized that fetal weight gain decreases from ~20 g/kg/d at 24–28 weeks of gestation to ~10 g/kg/d at 39–40 weeks (Table 32-1). Furthermore, the quality of the weight gain and the protein accretion rate also changes during the last trimester of pregnancy, and therefore nutritional requirements also vary in relation to GA (Table 32-1).[7]

Measurements of Inpatient Growth

Growth of preterm infants is usually evaluated by plotting the measurement of current weight, length, and head circumference on intrauterine growth charts according to GA up to the expected date of delivery and on term infant growth charts afterward. However, using two

different charts that do not perfectly overlap between 36 and 46 weeks GA make difficult the monitoring of growth during this period. To address this issue, specific gender-related fetal-infant growth charts for preterm infants were recently designed by merging intrauterine growth curves with the World Health Organization (WHO) growth standards for term infants.[8] Since these curves are available online for unrestricted use, it is likely that they will become widely used in clinical settings (Figure 32-1). Exact z-scores and percentile have also been made available online for download (http://ucalgary.ca/fenton).

Physiological Variation of Body Weight During the First Days of Life

The initial weight loss after birth is due to the postnatal physiologic contraction of extracellular compartment implying a reduction of body water content. In adequately breastfed term infant, it usually occurs during the first 2 to 4 days of life and corresponds to 5%–10% of birth weight, which is generally regained after 5 to 10 days.[9]

Because of the larger extracellular compartment of preterm infants, physiological postnatal weight loss is more frequently around 10% of birth weight and the time to regain birth weight is also longer (7–10 days). However, because of excessive insensible water losses and inability to concentrate urine, postnatal dehydration may rapidly occur in very preterm infants. High transcutaneous evaporative water losses during the first days of life are due to the immaturity of the skin barrier of the preterm infant. They are increased by low humidity environment, high ambient temperature, phototherapy, and by the use of a radiant warmer.[9] Because of the net water loss, postnatal dehydration of preterm infants is characterized by a weight loss above 10%–15%, which is frequently associated with hypernatremia above 150 mmol/L. Such dehydration with electrolytes disturbances should be prevented since it is associated with an increased mortality, higher rate of postnatal morbidities and long-term adverse developmental outcomes. On the other hand, high postnatal water supply and fluid overload also increase the mortality rate and the risk for adverse neonatal morbidities such as patent ductus arteriosus, bronchopulmonary dysplasia and necrotizing enterocolitis.[9,10] Therefore, careful monitoring of fluid and electrolytes homeostasis is required during the first week of life of very preterm infants. This includes daily assessment of weight, recording of fluid and electrolyte intake, and quantification of urine output. Insensible water losses may be estimated by

subtracting the urine output and the weight change from the total fluid intake. Regular determination of plasma and urine electrolyte concentrations may also be helpful to adapt intakes. Prevention of cutaneous insensible water loss is also essential to maintain fluid and electrolytes homeostasis (Table 32-2).

TABLE 32-1 Weight Gain, Lean Body Mass, and Protein Gain During the Last Trimester of Pregnancy and Theoretical Energy and Protein Requirements for Enteral Nutrition are Indicated by Gestational Age Group. Before 39 Weeks GA, Requirements Are Based on Fetal Growth, Fetal Accretion Rate, and Intestinal Absorption; After 40 Weeks, Requirements Are Based on the Composition of Human Milk

	Gestational Age, wks					
Parameters (per kg/d)	**<28**	**28–31**	**32–33**	**34–36**	**37–38**	**39–41**
Fetal growth						
Weight gain (g)	20	17.5	15	13	11	10
LBM gain (g)	17.8	14.4	12.1	10.5	7.2	6.6
Protein gain (g)	2.1	2	1.9	1.6	1.3	1.2
Requirements						
Energy (kcal)	125	125	130	125	115	110
Proteins (g)	4	3.9	3.5	3.1	2.5	2
Calcium (mg)	120–140	120–140	120–140	120–140	70–120	70–120
Phosphorus (mg)	60–90	60–90	60–90	60–90	35–75	35–75

LBM, lean body mass.

The values indicated do not take into account the nutrient supply needed to compensate for any nutritional deficit.

EUGR

EUGR, also called extra-uterine growth retardation, postnatal growth

restriction or postnatal growth failure, is a frequent clinical feature of preterm infants and particularly of the very, especially extremely premature ones. EUGR refers to a postnatal growth below that of the fetus of the same GA and is usually defined at hospital discharge if growth measurements are below the 10_{th} or the 3_{rd} percentile, or below -2 standard deviation (SD) on growth charts. Growth restriction can also be defined if a decrease of weight z-score >1 SD is observed during hospitalization. EUGR is inversely proportional to GA and birth weight and has been reported from all over the world at an incidence ranging from 40% to 90%.[2,11] Using weight as the unique parameter of postnatal growth may in fact underestimate the magnitude of EUGR. Indeed, linear growth is generally more severely affected than weight gain and preterm infants exhibit increased global and/or central fat mass, which can lead to lean body mass restriction.[12]

Consequences of Inadequate Perinatal Growth or Nutrition

Inadequate nutrition and/or undernutrition have long been suspected to be the main etiology of the observed EUGR of preterm infants and EUGR is observed when protein and/or energy intakes approach, but not reach, nutritional recommendations.[13] Significant relationships between poor in-hospital growth and adverse neurodevelopmental outcomes at 18 to 24 months' corrected age have been constantly demonstrated.[1,14] Furthermore, some studies suggest that this effect may last through childhood and adulthood.[15] These associations have been largely found for the smallest infants, whereas they appear insignificant in the larger babies. However, it should be noted that these associations are largely attenuated by adjustment for confounding factors (neonatal morbidity, socioeconomic factors, and level of education) and in-hospital head growth appears to better predict neurodevelopment than weight gain alone.[1,16,17]

Humidification of inspired gases
Use of plastic cover and/or plexiglass heat shields

Protein and energy intakes are the main nutritional determinants of growth, weight gain, and body composition. Protein-energy undernutrition during critical period of development has irreversible effects on organ development and affects brain size, structure, and function.[15,18] Failure to provide sufficient protein and energy during the first week of life may have significant short- and long-term impacts on postnatal morbidities, developmental indexes throughout infancy, childhood and adolescence.[19,20]

However, other nutrients may also affect psychomotor development without any effects on growth parameters, in particular long-chain polyunsaturated fatty acids (LC-PUFAs), iron, zinc, copper, iodine, selenium, vitamin A, choline, and folate.[4–6,21] Therefore, physicians should be aware that preterm infants are at risk of nutritional deficiency that may not be reflected by altered growth rate. Additionally, breastfeeding has been shown to be beneficial for neurological development of preterm infants despite the fact that breastfed infants initially grow at a lower rate than formula fed infants.[22–24]

Epidemiological studies have described other long-term health consequences of prematurity, including an increased risk of high blood pressure, insulin resistance and other determinants of cardiovascular diseases in adulthood.[3,25,26] Growth velocity between birth and expected term seems to have no significant effect on later blood pressure and metabolic syndrome while a reduced growth during hospitalization

significantly impact later development.[1,3,14,16,17,25] To date, there is a paucity of well-designed controlled studies on the effects of nutrition during hospitalization of preterm infants on the risk of hypertension or insulin resistance. Only the duration of breastfeeding has been shown to be associated with lower blood pressure, a 10% increase in human milk consumption conferring 0.3 mmHg reduction in mean arterial blood pressure after adjustment for identifiable confounders.[27] At present, no data support the hypothesis that interventions aimed at discouraging weight gain during hospitalization and after discharge would improve adult body composition and reduce the chance of developing hypertension or type 2 diabetes. It is therefore vital that preterm infants receive sufficient nutrients to prevent EUGR and impaired neurodevelopment.

NUTRITIONAL REQUIREMENTS

The paragraphs below aim to highlight the main issues regarding nutritional specificities and requirements for enteral nutrition of the preterm infant. Recent extensive reports on guidance on appropriate nutrient intakes and recommendations on enteral nutrient supply for preterm infants have been published and are depicted in Table 32-3. Although the recommended ranges of nutrient intakes are considered reasonable, a high degree of uncertainty still remains for many nutrients.

Energy

When considering energy requirements of preterm infants, postnatal metabolic needs, energy expenditure and nutrient losses must be added to nutrient accretion to evaluate requirements. The total metabolizable energy intake (including protein) is estimate to be 90–115 kcal/kg/d since it should cover the resting energy expenditure (45–50 kcal/kg/d), the energy expenditure due to physical activity and thermogenesis (10–20 kcal/kg/d), the cost of tissue synthesis (~15 kcal/kg/d), and the energy deposited in new tissue (20–30 kcal/kg/d). Some preterm infants with chronic disease such as bronchopulmonary dysplasia may have higher energy expenditure and, thus, require additional energy intakes. Taking into account an energy absorption rate of 85% with human milk and 90% with a well-absorbed formula, the energy requirement of preterm infants receiving enteral nutrition is between 110 and 135 kcal/kg/d.[4,28]

Protein

Nitrogen balances in very preterm infants have shown that obligatory nitrogen losses due to the high protein turnover correspond to 1–1.5 g/kg/d of protein and that much higher protein supply is needed to ensure anabolism and protein accretion comparable to the fetal accretion rate (i.e., 4.0 g/kg/d at 24–25 weeks and 3.3 g/kg/d at 30–32 weeks) (Table 32-1). The protein-to-energy ratio (PER) plays a major role in the quality of growth since high PER promotes higher lean body mass accretion instead of excessive fat mass deposition that is typically occurring with high energy intakes and low PER. Since the protein and energy requirements vary according to GA, recommended PER also varies. Recently, high protein requirements (4–4.5 g/kg/d in ELBW infants and 3.5–4 g/kg/d in VLBW infants up to 1800 g) with higher PER (3.6–4.1 g/100 kcal and 3.2–3.6 g/100 kcal, respectively) have been recommended in order to take into account the frequent cumulative protein deficit that occurred during the first weeks of life in preterm infants.[4,28] It should however be noted that PER >3.6 g/100 kcal have not been tested in clinical trials.

Lipids

The dietary supply of lipids provides the preterm infant with much of its energy needs. However, several factors affect fat absorption in preterm infants, which includes low enzyme secretion (gastric, pancreatic colipase-dependent triglyceride lipase, bile-salt-stimulated lipase (BSSL), pancreatic phospholipase A2), low luminal bile salt concentration, pasteurization (62.5°C for 30 minutes) of human position of fatty acids on the triglycerides, the length of carbon chain and the degree of saturation of fatty acids and pasteurization of human milk.[21] Medium chain triglycerides (MCT), which have high water solubility and are rapidly cleaved by lipases, are readily absorbed even in the presence of low intraluminal bile salts and pancreatic lipases and are therefore used in many enteral formulas for preterm infants. Further arguments for the use of MCT include carnitine-independent transport into the mitochondria and subsequent oxidation that is more rapid that for longer-chain fatty acids.[21]

Supply of LC-PUFAs are of concern because they are crucial for normal development of the central nervous system and have potential for long-lasting effects that extend beyond the period of dietary insufficiency.[21] The nervous system, and particularly the retina, is very rich in docosahexaenoic acid (DHA, C22:6n-3). Its accumulation starts in utero and proceeds during the first two years, when the growth and differentiation of the central nervous system are the most rapid. DHA supplementation of infant formula for preterm infants has consistently demonstrated better visual development compared with unsupplemented formulas. There is increasing evidence to suggest that LC-PUFAs supplementation for preterm infants is also related to improvements in more global measures of development, without any adverse effects. Given the limited and highly variable formation of DHA from alpha-linoleic acid (ALA, C18:3n-3), and because DHA is critical for normal retinal and brain development in the human, DHA is considered to be conditionally essential during early development. It is, however, important to note that

the DHA content of current preterm formulas is similar to the mean DHA content of human milk. However, recent studies have suggested that higher doses may be required to fulfill the needs and to support neurodevelopment of the preterm infants.[21,29] Finally, a concomitant intake of arachidonic acid (ARA, C20:4n-6) and a limited intake in eicosapentaenoic acid (EPA, C20:5n-3) are also recommended in order to prevent the distortion of the LC-PUFAs status and possible side effects (Table 32-4).[21]

Carbohydrates

There is a gradual increase in lactase activity with advancing gestation but overall, its activity remains low until about 36 weeks gestation. It is estimated that nearly 50%–70 % of the lactose ingested passes unabsorbed into the colon. Glucose polymers appear to be rapidly hydrolyzed and absorbed by the neonate and may be used to provide carbohydrates for preterm infants.

Minerals

Unfortified human milk (HM) provides about 6.4 mmol/L of calcium and 4.5 mmol/L of phosphorus. Assuming an intake of 160 ml/kg/d, this provides an intake of 1 mmol/kg/d of calcium and 0.72 mmol/kg/d of phosphorus, which are well below the fetal accretion rate (2.3–3.2 mmol/kg/d and 1.9–2.5 mmol/kg/d, respectively). Clinical studies have demonstrated that preterm infants fed unfortified HM develop osteopenia and metabolic bone disease of prematurity.[30] According to mineral balance studies, calcium retention is mainly dependent of calcium absorption and phosphorus availability. Calcium absorption is enhanced by vitamin D and usually varies between 50% and 65% of intakes depending on calcium salts bioavailability. Phosphorus is generally well absorbed by the gastrointestinal tract (~90%) but its availability for bone accretion is also dependent on the lean body mass accretion. Phosphate is a major constituent of the intracellular compartment and one gram of protein accretion is estimated to be associated with ~0.3 mmol of phosphorus retention. Hypophosphatemia (<1.6 mmol/L or 5 mg/dL) associated with low phosphaturia and hypercalciuria (with or without hypercalcemia) are typical biological signs of inadequate mineral intake and needs to be prevented.[30]

Considering a calcium to phosphorus ratio of 1.7 in bone hydroxyapatite and a need for 1.5 to 2.2 mmol/kg/d of calcium retention to

ensure appropriate bone mineralization, an enteral intake of 3–3.5 mmol/kg/d of highly bioavailable calcium salts and 2–3 mmol/kg/d of phosphorus is usually recommended.[4,30] Additionally, a vitamin D intake of 800–1,000 IU/d is required to obtain and maintain the 25-hydroxy vitamin D plasma concentration above 80 nmol/L (30 µg/L), ideally around 180 nmol/L (70 µg/L).

Fluids and Electrolytes

Considering physiological variation of body weight during the first days of life and frequent postnatal relative oliguria, fluid requirements of most term newborns on the first day of life are 40–60 mL/kg/d whereas that of preterm infants is higher, between 60 and 80 mL/kg/d, with no or little sodium, potassium, and chloride (<1 mmol/kg/d) intakes.[6,31] During the transitional period (i.e., day 2 to day 7–10 of life), fluid and electrolyte supply need to be progressively increased to reach requirements of the stable growing infants: 120–180 mL/kg/d, 3–7 mmol/kg/d of sodium, 2–5 mmol/kg/d of potassium, and 3–7 mmol/kg/d of chloride.[6,31]

ENTERAL NUTRITION

Enteral nutrition in preterm infants is challenging for several reasons, including gastrointestinal immaturity and the risk of necrotizing enterocolitis (NEC). NEC is a severe gastrointestinal disorder secondary to immature intestinal barrier function, altered gut microbiota, and excessive gut inflammatory response. It represents a major complication of prematurity and is associated with increased mortality and later neurodevelopmental disabilities.[32] The fear of NEC frequently leads to delayed introduction of enteral feeding and slow advancement of feeds, which consequently leads to an increase need for parenteral nutrition (PN). This practice, however, is not devoid of consequences. Enteral nutrition is essential to promote gastrointestinal growth and development by providing nutrients to the mucosal epithelial cells, stimulating the secretion of local growth factors and gastrointestinal hormones, and activating gastrointestinal neural pathways. Therefore, poor feeding induces gastrointestinal mucosal atrophy, abnormal mucus secretion, increased permeability, decreased regenerative capabilities, and finally, gastrointestinal dysfunction that may secondary increase the risk of feeding intolerance, bacterial translocation and NEC.[28,33] Furthermore, prolonged need for PN has its own associated complications, which

include metabolic intolerance, sepsis, thrombosis, cholestasis and inflammatory diseases. Therefore, optimizing feeding strategy in preterm infants is essential to reduce postnatal growth retardation and neonatal morbidities but also to improve long-term outcomes.

Mother's Milk and Donor's Milk

Preterm infants' breastfeeding has numerous beneficial effects such as promoting gastrointestinal maturation and intestinal tolerance and reducing the incidence of NEC, late-onset sepsis and hospital readmissions. Association between breastfeeding and improved mental, cognitive and psychomotor development, better visual acuity, increased total and white matter brain volumes and lower incidence of retinopathy of prematurity have also been demonstrated. Finally, breastfeeding also potentiality influences the risk for later metabolic syndrome and high blood pressure through adulthood.[3,34] The biological, immunologic, and nutritional characteristics of the human milk, which are described elsewhere in this book, likely explain most of these beneficial effects.

Mothers of preterm infants frequently encounter difficulties in initiating lactation and therefore appropriate counseling is needed. Breastfeeding education during pregnancy and lactation support by well-trained perinatal caregivers is essential for the success of breastfeeding in preterm infants. Nursing staff needs to help mother developing a plan for milk expression that meet her and hers baby's needs until breastfeeding can occur. Breast stimulation must be started within the first six hours after preterm delivery. Mother may express only a few drops initially and manual milk expressions work best for this small quantity. To better establish lactation, mothers need to use a double electric pump 8 to 10 times a day during session of 10–15 minutes. Nurses and pediatricians should favor skin to skin contact and encourage mothers to achieve adequate breast milk production after one week, 600 to 800 ml/d ideally. Expressed breast milk should be refrigerated or chilled right after it has been expressed. It is widely accepted that breast milk can be stored in a refrigerator for 72 hours and in a freezer for 6 months.[28,34,35]

When mother's milk is not available for feeding preterm infants, donor milk is an alternative to provide some of the advantages of breastfeeding. Donors are screened to avoid any risk of infection (HIV, CMV, hepatitis, syphilis) or any toxic contamination (drugs, alcohol, cigarettes). Donor milk is checked microbiologically and then pasteurized to avoid any bacterial or viral contamination. Pasteurization (62.5°C for 30 minutes) provides microbiological safety but induce some oxidative losses of

unsaturated lipids and vitamins, as well as inactivation of some enzymes and immunological factors such as IgA, lactoferrin, lysozyme. Some new techniques of heat treatment of milk are under investigation to improve the bioactivity of breast milk components while maintaining the safety concerns of donor milk.[36,37] Several systematic reviews have demonstrated the advantages of donor milk versus preterm formula in very preterm infants by reducing the incidence of NEC.[38,41] Therefore, when own mother's milk is not available, pasteurized donor milk is a good alternative for feeding the preterm infants.[28]

Human Milk Fortification

Feeding the preterm infant with unfortified human milk does not meet the infant's high nutritional requirements and leads to poor weight gain, osteopenia, nutritional deficits and potentially significant adverse outcomes. Multicomponent HM fortifiers (HMF) containing protein, energy, minerals and vitamins have therefore been developed and commercialized. Their use significantly improves postnatal weight gain, linear growth and head growth.[42–44] However, several studies have documented that many preterm infants fed with standardized fortification of human milk still suffer from EUGR. In some cases, this phenomenon is due to the low protein and energy content of the human milk which is not taking into account during the standardized fortification (Table 32-5). By using milk analyzers, it is now possible to adapt the level of fortification to the protein, fat and lactose content of human milk. Such individualized fortification has been shown to significantly improve postnatal growth of preterm infants.[43,44] In the absence of milk analyzers, fortification can also be adjusted to the blood urea nitrogen (BUN) concentration (target between 3.2 and 5 mmol/L) which is an intermediate marker of the adequacy of protein supply.[42] However, this adjustment does not completely prevent some nutritional deficit since it is performed *a posteriori*.

The addition of HMF increases milk osmolarity and, for most of the commercially available HMFs, introduces bovine proteins. In the past, some concerns have been raised that it may increase the risk of NEC but systematic reviews were not able to demonstrate any significant adverse effects related to the use of HMF.[45,46] Therefore, the benefits of fortification of human milk clearly outweigh the potential risks in very preterm infants. Full fortification must be performed in order to reduce the duration of PN and to improve overall nutritional intakes. It is generally

well accepted that full fortification is safe when enteral feeding reaches 100 mL/kg/d but recent data suggest that human milk fortification can be done earlier.[28,47,48]

Preterm Infant Formula

Although fortified breastfeeding is considered as the best feeding choice for preterm infants, mother's milk is not always available and many NICUs do not have access to a human milk bank or to donor milk. Therefore, specifically adapted formula for preterm infants have been developed and commercialized according to actual guidelines that are summarized in the Table 32-3.[4–6] The advantages of the preterm formula are numerous compared to term formula since they improve nutritional intakes and reduce nutritional deficit to allow proper growth of preterm infants. However, the data available still strongly support breastfeeding as the first choice for feeding preterm infants.

Initiation and Advancement of Enteral Nutrition

The gastrointestinal tract of the preterm infants at birth is characterized by an immature motility and/or dysmotility. This frequently leads to delayed gastric emptying, bile-stained gastric residuals and difficulties in passing stools. Because of these observations and the fear of NEC, it is sometimes common practice to delay enteral feeding and to use slow feeds advancement.

TABLE 32-5 Composition of Preterm Transitional, Preterm Mature and Term Mature Mother's Milk

Nutrients (Units/dL)	Preterm Transitional (6–10 d)	Preterm Mature (22–30 d)	Term Mature (>28 d)

TABLE 32-6 Reasonable Strategy to Optimize Enteral Feeding Practices in Low–Birth-Weight (<2500 g) Infants According to Their Birth Weight

Birth Weight	1500–2499 g	1000–1499 g	<1000 g
Milk	HM[a]	HM[a]	HM[a]
First feeding	As soon as possible	Between 6 and 48 h of life	Between 6 and 48 h of life
Initial feeding[b]	3–4 mL/kg q2h	1 mL/kg/h or 2 mL/kg q2h	0.5 mL/kg/h or 1 mL/kg q2h
Feeding advancement	20–40 mL/kg/d	20–30 mL/kg/d	15–25 mL/kg/d
HM fortification	Before 100 mL/kg/d	Before 100 mL/kg/d	before 100 mL/kg/d
Target enteral intakes	110–135 kcal/kg/d	110–135 kcal/kg/d	110–135 kcal/kg/d
	3.0–4.0 g/kg/d	3.5–4.0 g/kg/d	4–4.5 g/kg/d

HM, human milk; MEF, minimal enteral feeding

[a]Own mother breast milk or donor human milk, but adapted preterm infant formula may also be used if there is no access to human milk.

[b]Parenteral nutrition may be consider in 1500-2499 g infants according to their clinical situation but very low birth weight (<1500 g) infants most always require parenteral nutrition to meet their

nutritional needs.

Source: Adapted from Senterre.[28]

However, there is no evidence that withholding feeding decreases NEC or improves outcomes. In fact, delaying introduction of enteral feeding significantly increases the time to establish full enteral feeding, PN needs, and PN-associated morbidities.[28,49] Therefore, enteral feeding should be initiated as early as possible (Table 32-6). To achieve this goal, minimal enteral feeding (MEF) should be considered when neonatologists are tempted to delay enteral feeding introduction or to discontinue feeding because of specific clinical conditions (i.e., significant perinatal asphyxia, significant patent ductus arteriosus, hemodynamic instability, severe intra-uterine growth retardation, ELBW). MEF is defined by the administration of a constant volume of small feeds, usually ≤24 mL/kg/d, during a prolonged period of time (i.e., three to five days) in order to promote postnatal gastrointestinal maturation. It has been shown that early MEF improves nutritional intakes and growth, and avoid PN-associated diseases without increasing the risk of NEC. Therefore, the opportunity of early MEF should be evaluated as soon as infants' cardio-respiratory function is stabilized and after a few hours in all very preterm infants.[28,50]

Compare to slow feeds advancement (i.e., <24 mL/kg/d), advancement of 25–35 mL/kg/d in VLBW infants does not increase the risk of NEC and is associated with shorter time to regain birth weight and shorter time to achieve full enteral feeding.[28,51] Thus, feeding advancement of 20–30 mL/kg/d is generally considered reasonable in 1000–1500 g preterm infants according to feeding tolerance (Table 32-6). In those weighing less than 1000 g, the safety of such feeding advancement is not well established and 15–25 mL/kg/d advancement may be preferred until further studies are performed.[28]

Feeding Administration and Feeding Tolerance

Because of immaturity, oral feeding is frequently delayed in preterm infants and a prolonged period of tube feeding is generally required. Nasogastric tubes are easier to secure than orogastric tubes but may increase the work of breathing because of partial nasal airway obstruction.[28,52] Transpyloric tube feeding is sometimes used in case of severe gastroesophageal reflux but this practice is not recommended as a routine feeding method for neonates (Table 32-6).[28,53]

Conventional tube feeding consists of delivering intermittent bolus gavage by gravity over 10–30 minutes every two or three hours. In very

preterm infants, it seems that continuous feeding reduces gastroesophageal reflux symptoms and energy expenditure, improves postnatal gastrointestinal maturation and feeding tolerance and may accelerate the achievement of full enteral feeding.[28,54] Short interval feeding methods like one hourly intermittent gavage and slow intermittent gavage over one or two hours may also be proposed.[28]

The aspiration of gastric residuals is common practice to evaluate gastrointestinal tolerance while tube feeding. Most studies have considered gastric residuals as suspect if they are >3–4 mL/kg, >20%–50% of the previous feed, or bilious-stained. However, such studies evaluating the predictive value of such gastric residuals for significant feeding intolerance or NEC have demonstrated poor results. Therefore, in absence of any significant clinical signs or symptoms, the pretext of gastric residuals <4 mL/kg or <50% of three-hours previous feed should not be considered as valid to interrupt or reduce enteral feeding.[28,55] On the other side, any sign of potential feeding intolerance requires a complete clinical examination to determine subsequent care. An abdominal radiograph may be necessary to rule out NEC but non-irradiated techniques like abdominal ultrasounds are also useful to evaluate abdominal condition of preterm infants. When feeding intolerance is suspected or confirmed, feeds need to be adapted to each infant's evolution. If enteral feeding has been interrupted but clinical evolution rules out NEC or another disease, enteral feeding should be restarted as soon as possible, even after a few hours.[28]

Probiotics and Bioactive Factors

The gut microbiota of the hospitalized preterm infants is characterized by a delayed colonization and a low diversity. The predominant aerobes species are staphylococci (mainly coagulase -negative staphylococci), enterobacteria (mainly Klebsiella spp, Enterobacter spp), and enterococci whereas clostridia are the most common anaerobes. In contrast, Bacteroides and bifidobacteria seldom colonize preterm infants. Very little is known about factors that influence the colonization of the gut of very preterm infants. Colonization by bifidobacteria appears to be not only dependent on chronological age, but also by GA, suggesting that intestinal maturity is an important factor. In contrast to term infants, breastfeeding alone is unable to promote bifidobacteria colonization in preterm infants. Therefore, there is a great deal of interest for modulating the gastrointestinal microbiota of preterm infants using dietary components and microorganisms. Several studies have demonstrated that mortality and

incidence of NEC may be significantly lower in preterm infants receiving probiotics.[56] However, uncertainty remains on safety and choice of the bacterial strain(s), and therefore, the routine use of probiotics is not yet recommended.[57]

Breast milk contains many components that may act as bioactive factors, immunonutrients and growth factors. Among them, lactoferrin is a protein that has antimicrobial, host immunomodulatory and gastrointestinal effects. Supplementation with bovine-lactoferrin suggests some benefits with potential reduction of the incidence of nosocomial infections, especially fungal sepsis but further studies are needed to assess effective benefits, safety, ideal dose, and impact on both short- and long-term outcomes before routine use can be recommended.[58]

PN

PN is required in many preterm infants until full enteral feeding is established. Despite recommendations have been published years ago, there is a large discrepancy between daily recommended intakes and actual intakes during the first few weeks of life, resulting in substantial nutritional deficits.[59] It is essential that physicians acknowledge that preterm birth is a nutritional emergency. When required, PN initiation should not be delayed and should be initiated in most neonates in the first hours of life. The Table 32-7 summarizes the most recent international recommendations for PN in preterm infants.

To safely cover resting energy expenditure, prevent negative nitrogen balance and promote anabolism, a minimum energy intake of 40–55 kcal/kg/d with at least 1.5 g/kg/d of amino acids (AA) is recommended from the first day of life in all preterm infants.[6,60] However, much higher intake, especially of AA, can be used without signs of metabolic intolerance.[61] Routine initiation of PN within two hours of life with the supply of 2.4 g/kg/d of AA, 1 g/kg/d of lipid, and 6 g/kg/d of glucose (4–5 mg/kg/d) promote adequate postnatal weight gain in very preterm infants (Figure 32-2), and significantly reduces the incidence of EUGR.[47,62]

Lipid emulsions provide essential fatty acid and non-carbohydrate energy in a low volume and with low osmolarity. Evidences have accumulated lipid emulsions can also influence numerous pathophysiologic processes including oxidative stress, immune responses and inflammation. The use of the standard 20% emulsions, which contain a lower ratio of phospholipid emulsifier/triglycerides than standard 10%

lipid emulsion is recommended for preterm infants since it allows more efficient triglyceride clearance. Triglyceride levels in serum or plasma should be monitored particularly in cases with a marked risk for hyperlipidemia (e.g., patients with high lipid dosage, sepsis, catabolism, ELBW infants). Reduction of the dosage of lipid emulsions should be considered if serum or plasma triglyceride concentrations during infusion exceed 2.85 mmol/L (250 mg/dL).[60]

[a]To be reduced if hyperglycemia >8.3–10 mmol/(150–180 mg/dL).

[b]To be reduced if serum triglycerides >2.85 mmol/L > (250 mg/dL) and/or if hyperglycemia >8.3–10 mmol/L (150–180 mg/dL).

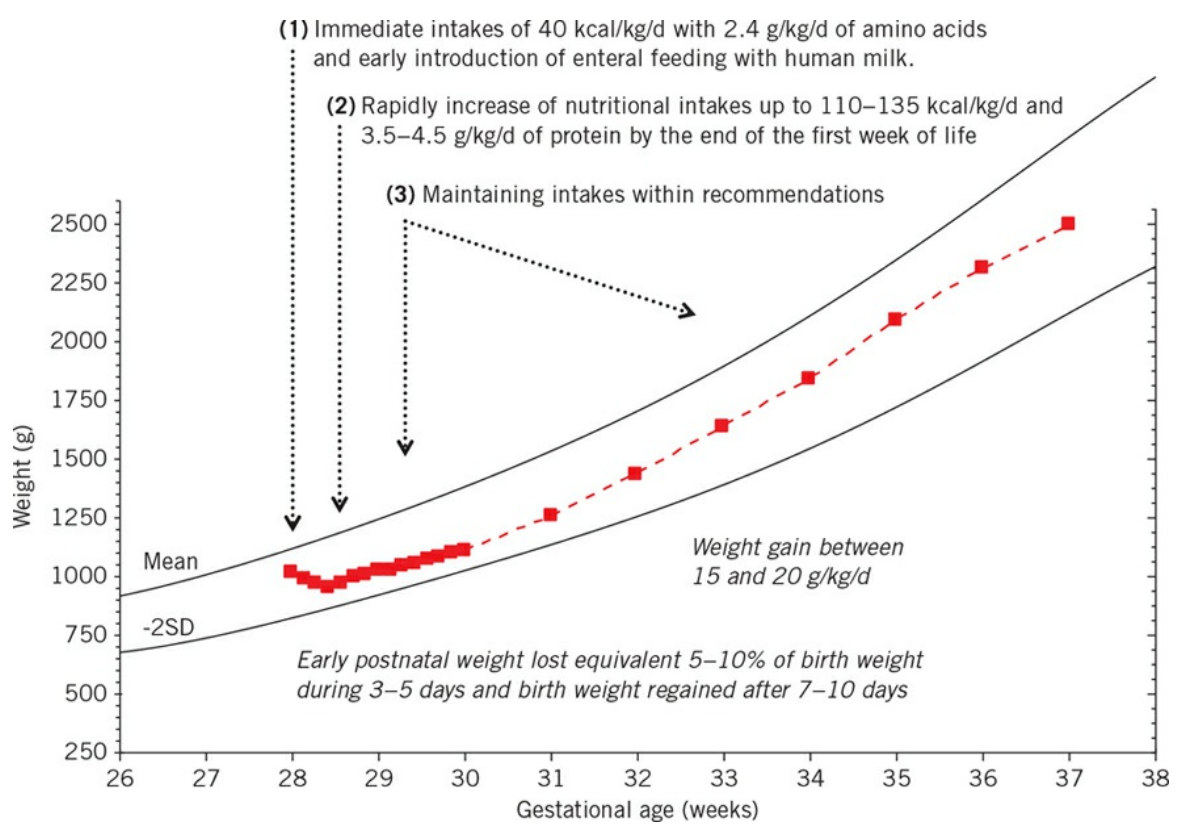

Figure 32-2 Optimizing nutritional support and postnatal growth from the first day of life onwards during postnatal hospitalization in very preterm infants. Adapted from Senterre.[47]

The adequacy of historical soybean lipid emulsions for the nutritional needs of newborn and preterm infants has been questioned, and a systematic study has demonstrated clinical benefits of lipid emulsions that are not purely soybean based (e.g., MCT-soybean, olive-soybean, or soybean-MCT-olive-fish emulsions).[63] Although these new lipid emulsions appear promising, further studies are required to determine the optimal lipid emulsions for preterm infants.[21]

Because of a combination of insulin resistance, relative insulin deficiency, high gluconeogenesis rate and the presence of risk factors (i.e., high glucose intakes, sepsis, NEC, drugs such as methylxanthines and corticosteroids, surgery, intrauterine growth retardation, and metabolic

stress) preterm infants are prone to hyperglycemia. The incidence of hyperglycemia during PN increased with decreased GA and birth weight and may reach 40%–80% in very preterm infants. Efforts are needed to avoid hyperglycemia as it has been associated with increased mortality and increased morbidity such as neurodevelopmental impairments and behavioral problems in infancy.[64] In practice, regular blood glucose monitoring is necessary. Euglycemia in neonates is usually considered for plasma glucose concentration between 2.5 and 8.3 mmol/L (45–150 mg/dL), and ideally between 2.8 and 6.7 mmol/L (50–120 mg/dL). Glucose intakes need to be adapted according to glucose tolerance up to 12–17 g/kg/d (8.5–12 mg/kg/min) but should not exceed maximal glucose oxidation capacity (18 g/kg/d, 12.5 mg/kg/min) and 60%–75% of non-protein energy intake. Any hypoglycemia in preterm infants should be treated rapidly and efficiently. In case of hyperglycemia >8.3 mmol/L, the first step is to understand the possible etiology (sepsis, stress, excessive glucose, or energy intakes) and measure potential glycosuria and the associated osmotic diuresis. Afterwards, the treatment of persistent hyperglycemia usually consists in reducing glucose infusion rate, stress factors, and lipid infusion rate. Protein intakes should not be decreased as AA infusion stimulates insulin secretion, and enhances glucose utilization. Insulin treatment can be started if hyperglycemia persists >10 mmol/L (180 mg/dL) with an initial dosage of 0.02–0.05 IU/kg/h.[60,64]

As described above, the modern nutritional approach for preterm infants is based on early initiation of enteral feeding and early PN in case of insufficient enteral intakes to rapidly meet their high nutritional requirements. The early feeding strongly influences the metabolism of potassium, phosphorus, and calcium, defining a syndrome that somehow simulates what happens in re-feeding conditions. Therefore, care should be taken to provide adequate amount of phosphorus and potassium during initiation of PN.[65]

Due to the very small diameter of blood vessels of preterm infants, the venous access is frequently uneasy and still represents an important challenge in clinical setting. Peripheral intravenous catheters do not allow the infusion of hyperosmolar PN solution, because of the risk of extravasation, dislodgement, leakage, and phlebitis. Venous umbilical catheters may be considered as a bridge procedure while awaiting placement of a long-term device. They allow administration of PN, medications and blood products during the first hours/days of life but this route should be as short as possible because of the risk of thrombotic complications. Peripherally inserted percutaneous central venous catheters

are the preferred route for prolonged PN in preterm infants. However, it must be remembered that intravascular catheters are a major source of coagulase-negative staphylococci bacteremia. This is particularly true in preterm infants for whom late-onset sepsis is one of the most common causes of morbidity and mortality.

CONCLUSION

Nutritional support in preterm and LBW infants is a major part of neonatal care and may have significant consequences on their neurodevelopment and future health. These infants have very specific nutritional requirements compared to term infants and optimizing the nutritional delivery in clinical setting is crucial. Enteral nutrition and breastfeeding needs to be initiated as soon as possible to promote gastrointestinal tract development and postnatal growth. Human milk confers many advantages to preterm infants, particularly for very preterm infants, but requires fortification to fulfill their nutritional needs. PN is an essential therapy for neonates who are not able to be completely enterally fed. Adequate protein and energy intakes are important from the first day of life and postnatal growth and metabolic homeostasis needs to be monitored closely.

Nutritional Management of Preterm Infants Post-Discharge

33

Mandy Brown Belfort, MD, MPH

INTRODUCTION

During the neonatal intensive care unit (NICU) hospitalization, nutritional management of the preterm infant aims to support growth and nutrient accretion equivalent to intrauterine rates. However, even when nutritional care meets or exceeds current guidelines, growth velocity during the NICU hospitalization frequently does not match that of the gestational age equivalent fetus[1] and many preterm infants are left with substantial growth and nutrient deficits at NICU discharge. Nutritional management of the post-discharge preterm infant is directed toward compensating for these deficits as well as supporting normal growth.

The first part of this chapter focuses on specific deficits that preterm infants accrue during the NICU hospitalization, typical patterns of growth that occur after discharge, and evidence regarding the impact of post-discharge growth patterns on long-term health and developmental outcomes. Next, specific post-discharge strategies to compensate for growth and other deficits at NICU discharge are reviewed.

GROWTH AND NUTRITIONAL DEFICITS AT NICU DISCHARGE

Preterm infants are typically discharged from the NICU between 35 and 40 weeks postmenstrual age (within a month of term equivalent). Nutritional

requirements after NICU discharge must address growth and nutrient deficits accrued prenatally and postnatally during the NICU hospitalization, and in addition to supporting normal post-term growth and nutrient accretion.

Deficits in Weight, Length, and Head Circumference

Prenatal deficits relate to intrauterine growth restriction, which is more common among fetuses subsequently born preterm than those who remain in-utero until term.[2] As demonstrated in several multi-center studies, postnatal weight gain, linear growth, and head growth in the NICU are substantially slower than growth of the gestational age equivalent in-utero fetus. This phenomenon is often referred to as "extrauterine growth failure." Notably, this postnatal growth failure occurs during the same developmental window as intrauterine growth failure occurs for an infant who is subsequently born growth restricted at term (Figure 33-1).

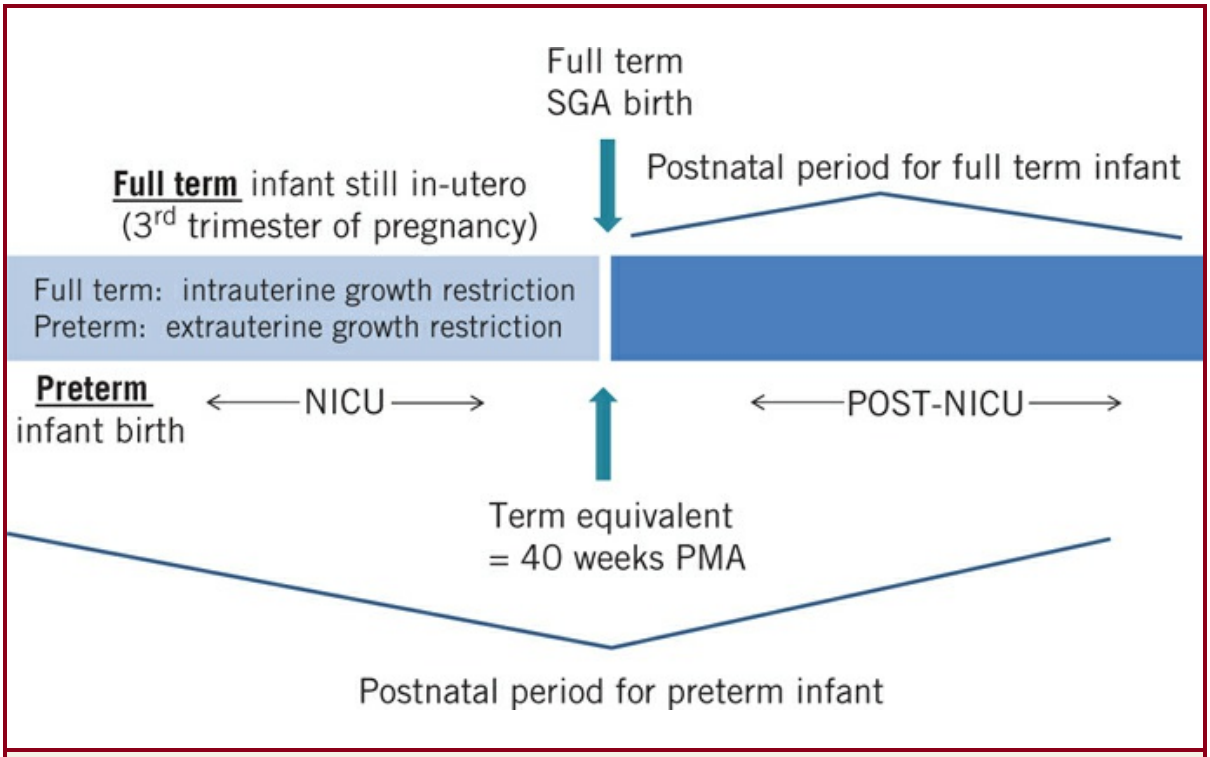

Figure 33-1 For the preterm infant, extrauterine growth restriction during the NICU hospitalization occurs with the same developmental timing as intrauterine growth restriction for the infant subsequently born small for gestational age (SGA) at term. PMA is postmenstrual age.

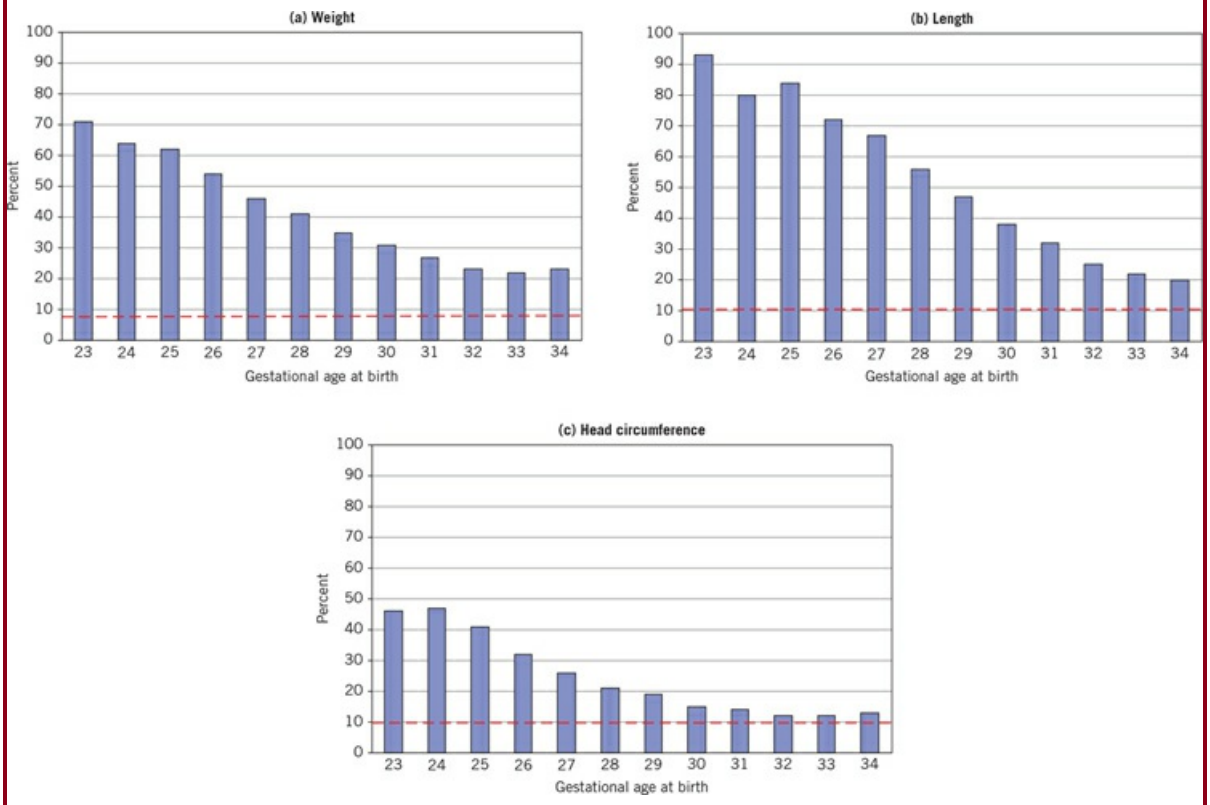

Figure 33-2 Percent of infants by gestational age with (A) weight (*n* = 23,873); (B) length (*n* = 17,203); and (C) head circumference (*n* = 20,885) <10th percentile at NICU discharge.[3] The dashed line represents the expected percent <10th percentile. The percent <10th percentile increases with decreasing gestational age at birth. From Clark.[3]

In one study[3] of infants 23–34 weeks' gestation at 124 US NICUs, 28% of infants had a discharge weight <10th percentile, 34% had length <10th percentile, and 16% had head circumference <10th percentile. The proportion with discharge size <10th percentile was higher for infants of lower gestational ages (Figure 33-2). Within gestational age categories, lower birth weight—reflective of fetal growth restriction—was associated with a higher proportion <10th percentile at discharge, underscoring the contribution of prenatally acquired deficits. Another study[4] of moderately preterm infants born at 30–35 weeks' gestation found that the mean weight *z*-score at birth was −0.16 but by discharge had fallen to −0.87; length and head circumference data were not reported. Growth outcomes varied considerably between NICUs, possibly reflecting differences in feeding practice. In sum, preterm infants are often born after a period of

intrauterine growth restriction, and postnatally in the NICU accumulate additional, substantial deficits in weight, length, and head circumference relative to the appropriately grown, full-term infant at birth.

Body Composition Differences

Deficits in body size at NICU discharge are accompanied by notable differences in body composition between preterm infants and their full-term counterparts. A recent systematic review and meta-analysis[5] summarized the data from nine studies on this topic. While total body fat percent was higher among preterm infants at term equivalent age vs. full-term infants at birth, fat-free mass was substantially lower (Table 33-1). Results of two studies[6,7] not included in the meta-analysis were largely similar. Another study[8] not included in the meta-analysis compared 67 small-for-gestational-age (SGA) preterm (≤34 weeks' gestation) infants at term equivalent age with 132 SGA full-term infants, and found that while the groups had similar weight (2403 vs. 2314 g), the preterm infants were shorter (45.3 vs. 48.1 cm) and had a substantially higher percent fat mass (14.3% vs. 5.8%) than the full-term infants. The observed fat mass difference of 8.5% in SGA infants was more pronounced than differences previously observed between appropriate-for-gestational-age (AGA) preterm and full-term infants. In sum, as compared with full-term infants at birth, preterm infants at NICU discharge have substantially greater adiposity and less fat-free mass than their full-term counterparts, and this difference may be more pronounced for SGA preterm infants. It is possible that the greater adiposity reflects an imbalance of protein: energy in the NICU diet as compared with the intrauterine environment, favoring the deposition of adipose tissue rather than lean mass.[9–11]

Energy and Protein Deficits

In addition to anthropometric differences, total energy deficits are important to quantify because postnatal energy intake is a key determinant of weight gain, in one study[12] accounting for 45% of the observed variation in weight *z*-score change from birth to 5 weeks. That study estimated that for infants born <30 weeks' gestational age, the cumulative energy deficit after five weeks in the NICU is 813 ± 542 kcal/kg. The estimated deficit was less (382 ± 263 kcal/kg) for infants born <30 weeks.

TABLE 33-1 Summary of Meta-Analyses of Studies Describing Differences in Body

Composition and Size Between Preterm Infants at Term Equivalent and Full-Term Infants at Birth				
Outcome	**Number of Studies (Participants)**	**Direction of Effect**	**Mean Effect Size (95% CI)**	**P-Value**
Total body fat %	7 (672)	Preterm > term	3% (0.25%, 5.88%)	0.03
Fat mass	5 (297)	Preterm < term	−50 g (−90 g, −10 g)	0.02
Fat free mass	3 (137)	Preterm < term	−460 g (−340 g, −270 g)	<0.0001
Weight	7 (577)	Preterm < term	−560 g (−750 g, −440 g)	<0.0001
Length	4 (383)	Preterm < term	−3.7 cm (−4.6 g, −2.8 g)	<0.0001
Head circumference	5 (450)	Preterm < term	−1 cm (−1.5 g, −0.5 g)	<0.0001

Source: From Johnson.[5]

In addition to deficits in energy, even with contemporary preterm formulas and human milk fortification, specific macro- and micronutrient deficits accrue prior to NICU discharge, which are relevant for post-NICU nutritional strategies. In one study,[12] typical protein deficits accumulated over five postnatal weeks were estimated at 23 ± 12 g/kg for infants <30 weeks, and 13 ± 15 g/kg for infants ≥30 weeks.

Mineral Deficits

Preterm infants are born before completing the third trimester of gestation, an important period for fetal accretion of minerals including calcium, phosphorus, and iron. Because postnatal enteral and parenteral nutrition rarely achieve fetal accretion rates despite routine fortification of preterm formula and human milk, at NICU discharge preterm infants may face residual deficits. Deficits in calcium and phosphorusare reflected by the lower bone mineral content seen in preterm infants at discharge, as compared with full-term newborn infants.[13] Regarding iron, in addition to missed fetal accretion, the preterm infant often experiences substantial iron losses related to phlebotomy in the NICU, exacerbating the deficit at NICU discharge.

Deficits Specific to Human Milk Fed Infants

Human milk is considered the normative food for all infants, including those born preterm[14]; however, human milk requires fortification to meet the nutritional requirements of the growing preterm infant during the NICU hospitalization. Even despite fortification, at NICU discharge, many preterm infants fed predominantly human milk face greater nutritional deficits than formula fed infants. These deficits are directly relevant to strategies for post-NICU nutrition for breast-fed infants. Specific deficits associated with the use of donor human milk are particularly important to consider given its rising use in the United States.[15]

Several contemporary single center studies suggest that at NICU discharge, human milk-fed infants have greater growth deficits than formula fed infants, despite appropriate fortification of human milk. In one,[16] as compared with infants fed <25% human milk, infants fed >75% human milk gained less weight (*z*-score change from birth to discharge −0.6 vs. −0.1 based on an external fetal growth reference,[17] Figure 33-3). In another,[18] weight, length, and head circumference were all smaller for infants who were fed predominantly breast milk in the NICU as compared with formula fed infants.

Donor human milk is used increasingly[15] during the NICU hospitalization to supplement mother's milk when it is inadequate or not available. Both observational and experimental evidence suggests that despite fortification, donor milk feeding during the NICU hospitalization is associated with poorer growth as compared with mother's milk feeding, either exclusively or with formula supplementation. In one observational study, among predominantly human-milk-fed infants, weight gain was slower for infants fed >75% donor human milk vs. >75% mother's milk (*z*-score change −0.84 vs. −0.56). In a randomized trial[19] of donor human milk vs. preterm formula to supplement mother's milk in the NICU, infants supplemented with donor milk had slower weight gain (20.1 g/kg/d vs. 17.1 g/kg/d), likely an underestimate of the true difference since 21% of infants initially assigned to the donor human milk group crossed over to the preterm formula group due to poor weight gain. Pasteurization of donor human milk inactivates several lipase enzymes normally present in breast milk,[20] which may limit digestion and absorption of fat and partially explain the slower weight gain observed in donor milk fed infants. Donor milk may also contain less DHA than mother's milk, contributing to a deficit in this important fatty acid.

Summary

The preterm infant faces growth and nutrient deficits acquired prenatally, followed by deficits acquired postnatally during the NICU hospitalization. These deficits are reflected in the preterm infant's smaller body size at term equivalent, as compared with the full term infant at birth, and are accompanied by energy deficits and deficits in accretion of protein and minerals. Preterm infants at term also have a greater proportion of adipose rather than lean mass relative to their full term counterparts. Finally, human milk fed infants, particularly those infants fed donor human milk, typically leave the NICU with more marked nutritional deficits than preterm infants fed formula. Nutritional support after NICU discharge must compensate for these deficits, in addition to supporting normal longitudinal growth.

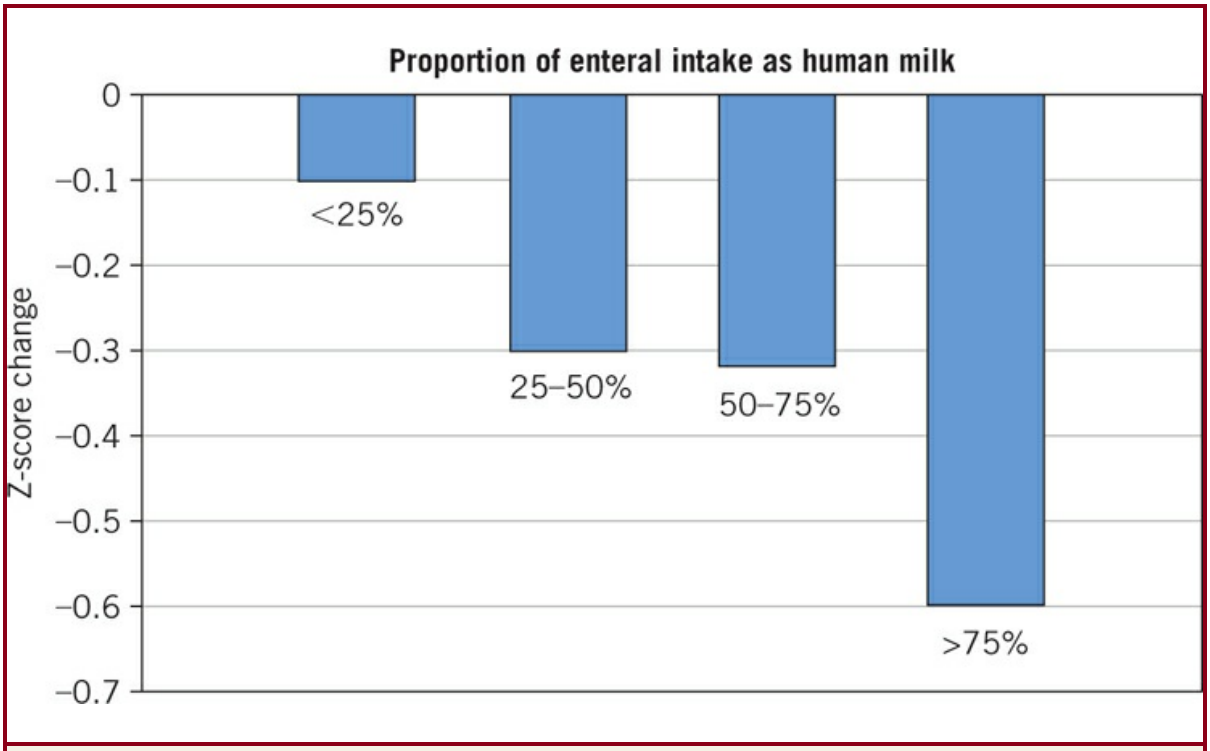

Figure 33-3 Weight z-score change from birth to NICU discharge according to proportion of enteral intake as human milk. Infants who received more human milk had a greater weight deficit at NICU discharge. From Colaizy et al.[16]

PATTERNS OF POST-DISCHARGE GROWTH

Several longitudinal studies have reported growth patterns of preterm infants post-discharge. Studies of older cohorts have the advantage of

following children to young adulthood, but reflect outdated nutritional practices. More recent studies reflect current practices, but lack long-term outcome data. Important considerations with respect to patterns post-NICU growth include timing of catch-up from deficits accrued prenatally and postnatally in the NICU; the influence of SGA status on post-NICU growth potential; sex differences; and changes in body composition over time, specifically differences in adiposity vs. lean mass.

Hack and colleagues[21] followed a US cohort of 195 VLBW infants born in 1977 to 1979 from birth to 20 years of age. In that cohort, catch up in weight after term began in early infancy, but was incomplete by 20 months (weight *z*-score increase from −1.79 to −1.16 in males; and from −1.12 to −0.82 in females). The pattern of early catch up in linear growth was similar with length *z*-scores increasing from −2.56 to −0.55 in males and −1.22 to −0.16 in females. At age 8 years, as compared with full-term controls, both males and females remained lighter (males by 4.3 kg; females, 3.6 kg) and shorter (males by 3.9 cm; females, 2.9 cm). By age 20 years, weight and height were similar for preterm vs. control females, but not males, who were 10.5 kg lighter and 3.1 cm shorter than controls. Body mass index (BMI) at age 20 years was 2.6 kg/m^2 lower for preterm vs. control males, but not different among females. Among males but not females, SGA infants were more likely to be of subnormal size at age 20 years than appropriately grown infants, for example 32% SGA vs. 6% AGA males were of subnormal weight and 21% SGA vs. 4% AGA males were of subnormal height (Figure 33-4).

Similarly, a Dutch study[22] of 1338 children born <32 weeks or <1500 g in 1983 similarly observed persistent stunting at age 10 years in SGA but not AGA infants. In a Canadian cohort of 147 extremely low birth weight (ELBW, <1000 g) born 1977 to 1982, after a period of decline in weight *z*-score from birth to 1 year, catch-up in both weight and length/height continued through infancy, childhood, and adolescence.[23] By young adulthood (age 23 years), ELBW participants remained somewhat lighter and shorter than full-term controls, but BMI was similar suggesting that gains in weight and length/height were proportional. An Australian study[24] of VLBW infants born in 1977 to 1982 also described substantial catch-up in weight and height by age 14 years relative to normal birth weight controls, but with a persistent deficit in weight (*z*-score −0.14 for infants born <1000 g) and height (*z*-score −0.43 for infants born <1000 g and −0.11 for infants born 1000–1499 g). Taken together, these data from older cohorts followed to adolescence and young adulthood suggest that catch-up in weight and height continues through adolescence, but may be

incomplete by early adulthood in some, particularly males and SGA infants.

A more contemporary cohort of 1151 US ELBW infants born in 1993 and 1994 was evaluated at 36 weeks postmenstrual age and again at 18–22 months. At 36 weeks postmenstrual age, virtually all infants had weight <10th percentile as compared with national normative standards. By 18–22 months, 40% of infants born at 600–1000 g remained <10th percentile for weight.[25] Correlates of poorer postnatal weight gain included SGA status and lower birth weight. Another US cohort of 154 ELBW infants born between 1997 and 1999 was studied through 20 months, at which time the mean weight *z*-score was −1.56, length −0.87, and head circumference −0.55, reflecting incomplete catch-up to their full-term peers.[26] A larger (*n* = 1320), population-based German VLBW cohort born in 1998 and 1999 was followed to age 6 years. As compared with a reference population, the VLBW children showed continued but incomplete catch-up in weight and length from 0.8 months through 6 years of age.[27] For example, height *z*-score increased from −0.75 to −0.62 at 6 years in that time interval. Preterm SGA infants remained lighter (weight *z*-score −1.09 vs. −0.54) and shorter (height *z*-score −0.78 vs. −0.48) than their AGA counterparts. These data suggest that even in more contemporary cohorts, VLBW and particularly ELBW infants remain substantially lighter and shorter in late infancy and at school age than their full-term counterparts.

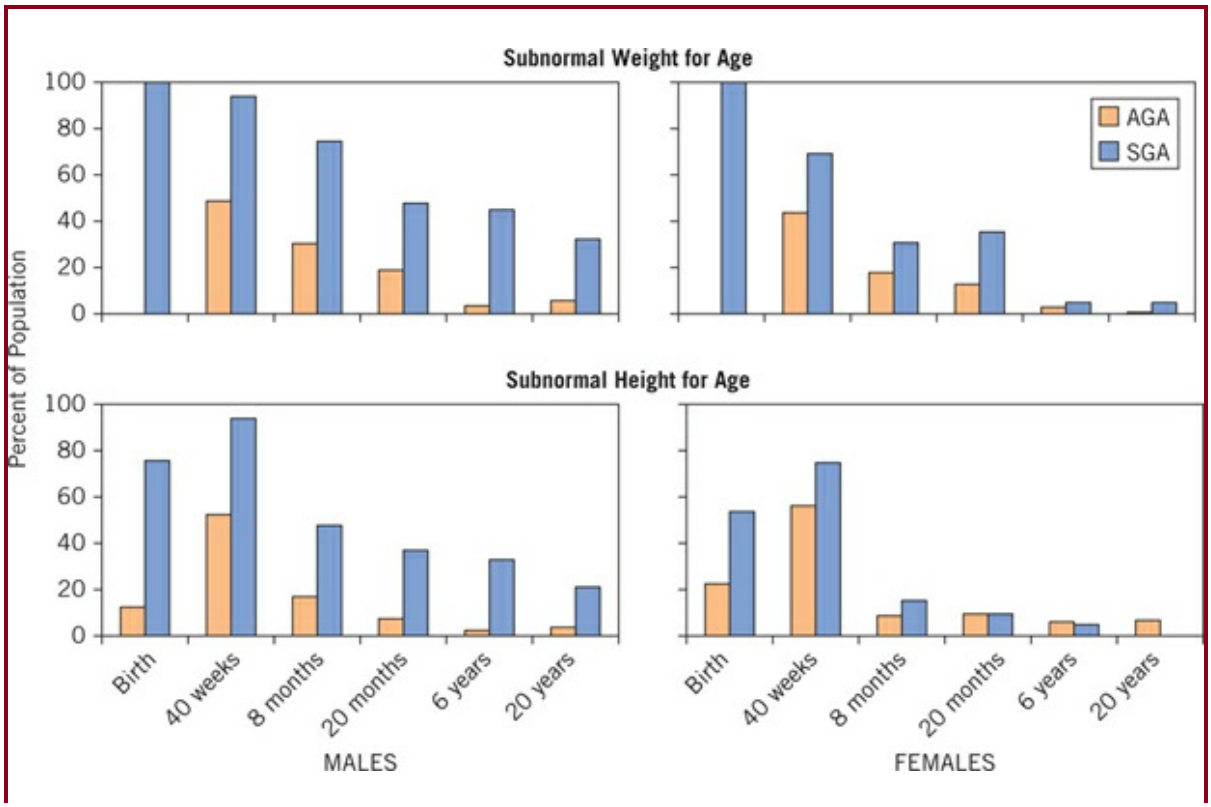

Figure 33-4 Weight *z*-score change from birth to NICU discharge according to proportion of enteral intake as human milk. Infants who received more human milk had a greater weight deficit at NICU discharge. From Hack et al.[21]

Limited data exist regarding post-NICU changes in body composition. In one study[28] of 26 preterm (<35 weeks' gestation) and 97 full-term infants—all of whom were appropriately grown at birth—assessed at term equivalent, preterm infants were lighter and shorter, and had higher body fat percent (18.7% vs. 15.1%, P <0.0001); by 4 months corrected age, weight and length were similar, and body fat percent was still higher among preterm infants, but the difference was no longer statistically significant (27.7% vs. 23.9%, P = 0.07). Further study regarding adiposity and lean mass trajectories of preterm infants after NICU discharge may be informative about optimal patterns of growth.

Summary

Many preterm infants catch up to their full term counterparts in weight and length during the first two years after NICU discharge. Most have caught up by school age, although some show continued catch-up growth through adolescence. Males and infants born SGA are at risk for deficits in weight and height that are still apparent in early adulthood. In terms of body composition, data are limited as to whether the greater fat percent seen at NICU discharge persists into the post-discharge period.

SHORT- AND LONG-TERM EFFECTS ON POST-DISCHARGE GROWTH

While longitudinal studies demonstrate that preterm infants experience poorer growth after NICU discharge than their full-term counterparts after birth, the optimal pattern of post-NICU growth is not known. Assessing the impact of early growth and nutrition on long-term health and developmental outcomes can inform recommendations for post-NICU growth targets. Specific long-term considerations include maximizing neurodevelopmental potential while also addressing emerging concerns about adverse effects of promoting rapid infant growth on later cardio metabolic health.

Post-Discharge Growth and Neurodevelopment

Weight gain during the NICU hospitalization is an important determinant of later neurodevelopmental outcome[29,30] but relatively few studies have examined the impact of infant growth after NICU discharge. In one single-center study,[31] greater weight gain and linear growth in the first two years were associated with higher developmental scores at age 2 years. In a multi-center US cohort of preterm, low-birth-weight infants born in the 1980's, higher IQ at age 8 years was associated with greater weight gain (2.1 points per SD, 95% CI 1.1, 3.1) and linear growth (2.4 points per SD, 95% CI 1.3, 3.5) from term to 4 months corrected age.[32] Another study[33] of the same cohort found that adequate postnatal weight gain was particularly important for preterm infants with fetal growth restriction. Similarly, in a contemporary (born 2001–2005) Australian cohort, greater weight gain and linear growth from term to 4 months were associated with better motor scores at 18 months.[34] Of note, post-NICU weight gain out of proportion to linear growth did not appear to benefit neurodevelopment, whereas during the NICU hospitalization, excess weight gain appeared to be beneficial.

Post-Discharge Growth and Cardio Metabolic Health

Several recent studies demonstrate that preterm infants are at heightened risk for developing cardio metabolic diseases in adulthood. Finnish, Dutch, and New Zealand groups have reported greater insulin resistance in preterm as compared with full-term adolescents and young adults,[35–37] and preterm infants appear to be 60% more likely to develop type 2diabetes.[38] A meta-analysis found that in adolescence and young adulthood, systolic blood pressure of former preterm infants is approximately 2.5 mmHg higher than full-term infants.[39] Adults born preterm are about twice as likely to be hypertensive as those born full term.[40]

It is possible that promoting rapid postnatal growth may be harmful to cardio metabolic health.[41,42] In terms of later hypertension, while little experimental evidence exists specifically regarding post-NICU growth, some[32,35] but not all[43,44] observational studies of post-NICU growth suggest a possible link with later, higher blood pressure. In terms of insulin resistance, a Dutch study of 345 infants <32 weeks and/or <1500 g reported a weak association of weight gain through 3 months of age with the log insulin concentration on fasting blood specimen at age 19 years, but no association with c-peptide or log HOMA-IR levels (homeostatic model assessment of insulin resistance).[45] Further study of a subset (*n* =

37) of the same cohort at age 21 years revealed that children in the lowest quartile of insulin sensitivity had been longer at 12 months and heavier at 24 months, as compared with children in the highest quartile of insulin sensitivity; these results reflect birth weight as well as weight gained after birth. More rapid infant weight gain in preterm infants has also been linked with obesity at age 8 years (odds ratio 2.7, 95% CI 1.9, 3.9 per 100 g additional weight gain in the first year),[46] with higher BMI (0.2 SD per SD additional weight gain from birth to 3 months), and with greater body fat and abdominal fat percentage as measured by dual-energy x-ray absorptiometry (DXA) at age 19.[47]

Summary and Recommendations

In sum, observational data suggests that promoting more rapid weight gain, and specifically linear growth, after NICU discharge may benefit long-term neurodevelopmental outcomes, but rapid weight gain, particularly out of proportion to linear growth, may also increase the risk for adverse cardiometabolic effects. We recommend that clinicians caring for preterm infants after NICU discharge monitor weight gain and linear growth over time, plotting measurements on a growth curve such as the World Health Organization (WHO) Child Growth Standards (Appendix A). The WHO Child Growth Standards have the advantage over other growth curves of providing BMI-for-age curves for boys and girls from birth to 2 years, which can help identify excess weight gain out of proportion to linear growth, even in infancy. Plotting measurements for both chronologic and corrected age is helpful in monitoring catch-up from extrauterine growth failure experienced during the NICU hospitalization (Figure 33-5). Corrected age can be calculated using online calculators such as the one found at this website http://www.vtoxford.org/research/elbw/calc/readme.aspx.

INTERVENTIONS TO SUPPORT POST-DISCHARGE GROWTH

Given the substantial deficits that preterm infants experience at NICU discharge, combined with observational evidence associating more rapid post-NICU growth with beneficial neurodevelopmental outcomes, nutritional strategies to promote more rapid growth are of interest. For formula-fed infants, various strategies of supplementing protein and minerals (particularly calcium and phosphorus) with or without additional

calories have been examined. For breast milk fed infants, strategies to supplement breast milk have been proposed, although data about the benefits and risks are sparse. Relevant outcomes to consider include both short term (growth, safety) and longer term (neurodevelopment, cardio metabolic).

Energy and Nutrient Enrichment of Infant Formula After NICU Discharge

Whereas standard term formulas are based on the composition of mature human milk, in-hospital preterm formulas are typically enriched with energy, protein, and minerals, vitamins, and trace elements in amounts estimated to support intrauterine accretion rates. Post-discharge formulas are also enriched relative to term formulas, but generally provide less energy, protein, and minerals than in-hospital preterm formulas (Table 33-2). Studies have examined both preterm and post-discharge formulas for use in preterm infants after NICU discharge.

A recent Cochrane review[48] addressed randomized trials of feeding nutrient-enriched rather than standard full-term formula after NICU discharge (Tables 33-3 and 4). Of 15 relevant trials, 10 compared a post-discharge vs. term formula, whereas 5 compared an in-hospital preterm vs. term formula. Outcomes included growth, development, and bone mineralization. As compared with infants fed term formula, at 9 months of age those fed post-discharge formula were on average 244 g heavier and 7.3 mm longer, but by 12 and 18 months, no weight or length differences were noted (Table 33-3). In contrast, at 18 months, infants fed preterm formula after NICU discharge remained 490 g heavier and 11 mm longer (Table 33-4). Feeding preterm formula also led to better head growth (by 5.4 mm at 18 months) than term formula, but post-discharge formula did not. No significant differences were noted in neurodevelopmental outcome to 12 months or in body composition. Only one study of post-discharge vs. term formula examined bone mineralization, and found increased bone mineral content by DXA at 9 months in infants fed post-discharge formula (difference 20.6 mg/cm). Cardio Metabolic outcomes such as body mass index and blood pressure were not reported. In sum, there is little evidence to support a sustained beneficial effect of post-discharge formula on growth in infancy, although there may be a short-term benefit to bone mineralization. Continued feeding of preterm formula after NICU discharge may confer short term benefits on growth. Data are lacking on long-term neurodevelopmental benefits as well as adverse cardio

metabolic effects of feeding nutrient-enriched formulas to preterm infants after NICU discharge.

Isocaloric Nutrient Enrichment of Infant Formula After NICU Discharge

Because of the concern that providing excess energy after NICU discharge could lead to excess fat but not lean mass accumulation, it is relevant to examine the effect of supplementing protein and minerals but not energy after NICU discharge. One small (n = 37) study[49] compared a formula with added protein (2.2 vs. 2 g/100 mL) and minerals (e.g., calcium, 100 vs. 80 gm; phosphorus, 60 vs. 42.5 mg) vs. a standard term formula starting in the NICU and continuing to term equivalent. The enriched and control formulas were isocaloric. At hospital discharge, infants were similar in weight, length, and head circumference. By term equivalent, infants fed the enriched formula were on average 231 g heavier, with no differences noted in length or head circumference. At hospital discharge and by term equivalent, infants fed the enriched formula had greater bone mineral content measured by DXA (difference at term equivalent, 3 g/kg body weight), but similar fat mass and lean mass percent. Whether there were longer term effects on bone mineral content or other aspects of body composition was not assessed.

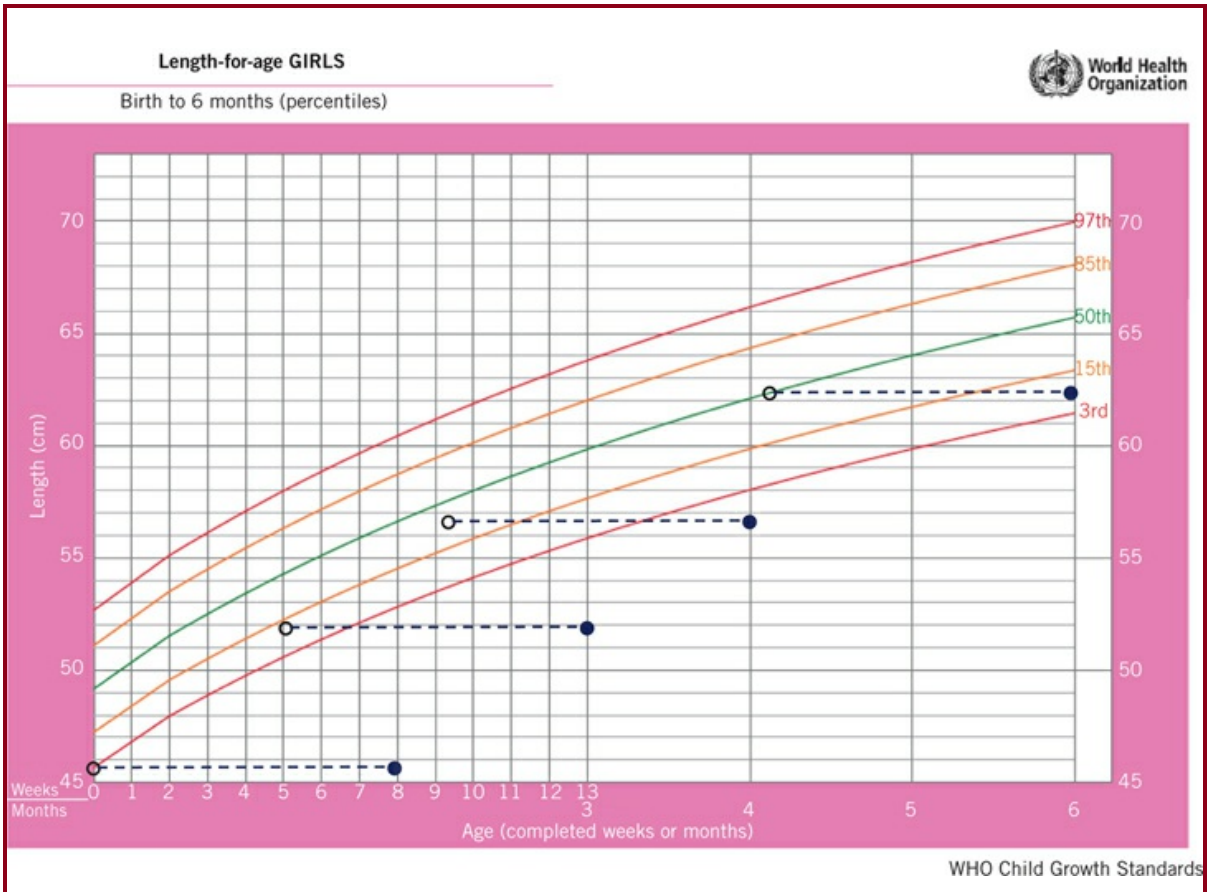

Figure 33-5 Example of post-NICU length measurements plotted for chronologic and corrected age on the World Health Organization Child Growth Standards. Filled circles indicate chronologic age and open circles indicate corrected age. In this example, the child was born at 32 weeks' gestation, or 8 weeks preterm. For 8 weeks chronologic age, length is well below the 3rd percentile, but for the corrected age of term, length is at the 3rd percentile. By 6 months chronologic age, the length-for-chronologic-age is between the 3rd and 15th percentiles, whereas for the corrected age of just over 4 months, length is at the 50th percentile.

Another study[50] compared two isocaloric formulas, one with more protein (1.70 vs. 1.47 g per 100 mL) and therefore a higher protein/energy ratio (2.75 g/100 kcal vs. 2.54 g/100 kcal). Calcium (65 vs. 50 mg), phosphorus (38 vs. 30 mg), DHA (14.0 vs. 6.7 mg), and several other nutrients were also different between the formulas. The trial was continued to 6 months of age. While weight and length at 6 months were similar between the groups, infants fed the enriched formula gained more lean

mass and less fat mass, as measured by DXA. Of note, a reference group of human milk fed infants gained less lean mass and more fat mass than either of the formula fed groups. Longer term outcomes were not reported.

Enrichment of Human Milk After NICU Discharge

While evidence is limited to support the multi-nutrient fortification of infant formula after NICU discharge, given the greater nutritional deficits accumulated by breast milk fed vs. formula fed infants during the NICU hospitalization and the relatively low protein content of mature human milk, post-discharge fortification of breast milk is considered separately. Fortifying breast milk has the potential to compensate for deficits specific to breast milk fed infants while allowing continued breastfeeding according to national and international recommendations.

TABLE 33-2 Comparison of Human Milk With Typical Term, Post-Discharge Preterm, and In-Hospital Preterm Formulas

	Mature Human Milk	Term Formula	Post-Discharge Formula	In-Hospital Preterm Formula
Energy (kcal)	650–700	680	740	810
Protein (g)	9	14	21	24
Fat (g)	35	36	39	41
Carbohydrate (g)	67	74	79	90
Calcium (mg)	200–250	530	890	1340
Phosphorus (mg)	120–140	290	490	670
Iron (mg)	0.3–0.9	12.2	13.3	14.4
Zinc (mg)	1–3	6.8	9	12.2
Sodium (mEq)	5.2–10.9	8	11.3	13.9
Vitamin A(mg)	0.3–0.6	2000	3330	10,100
Vitamin D (mcg)	0.33	410	590	2200
Vitamin E (mg)	3–8	13.5	30	51

Approximate content per liter.

TABLE 33-4 Cochrane Meta-Analysis of In-Hospital Preterm Versus Standard Term Formula After NICU Discharge: Effects on Growth

	Age at Follow-Up				
	3–4 Months	6 Months	9 Months	12 Months	18 Months
Weight (g)	74.4 (−267.1, 415.9)	74.6 (−164.7, 313.9)	112.0 (−482.7, 706.7)	539.5 (255.0, 823.9)	490.8 (142.2, 839.4)
Length (mm)	−2.3 (−13.1, 8.6)	1.8 (−6.3, 9.9)	−3.0 (−17.0, 11.0)	5.1 (−4.2, 14.5)	11.0 (1.9, 20.1)
Head circumference (mm)	3.61 (−2.1, 9.3)	5.8 (1.3, 10.3)	8.0 (0.9, 15.2)	6.1 (1.1, 11.1)	5.4 (0.7, 10.1)

Numbers are mean differences (95% confidence intervals). Positive numbers indicate a beneficial effect of the preterm formula.

Source: From Young.[48]

In contrast to evidence that fortified formula is of little benefit to growth after discharge, limited evidence suggests that fortifying human milk in the initial months after NICU discharge has a sustained benefit to growth. In one small (n = 39) study,[51] infants <33 weeks' gestation receiving predominantly (≥80%) human milk at the time of discharge were randomized to fortify half the daily feedings with a powdered multi nutrient human milk fortifier for 12 weeks vs. no fortification. At 12 weeks, infants in the fortification group were longer and had larger head circumferences as compared with control infants. Growth benefits persisted to 1 year,[52] with infants who received fortified milk approximately 1.2 kg heavier and 3.8 cm longer than control infants. Head circumference at 1 year was 1 cm larger for infants who received fortification (not statistically significant). Results also suggested better neurodevelopment in the fortification group. At 1 year, the Bayley mental development index score was 9 points (~2/3 standard deviation) higher for intervention infants, although the study was not powered for that outcome. Early visual acuity at 4 and 6 months was also better in the fortified infants,[53] although it is unclear to what extent the subtle differences observed represent clinically important neurodevelopmental differences. Taken together, these data support fortification of human milk after NICU discharge to promote better growth and neurodevelopment; however, the extent to which benefits persist beyond infancy is unknown.

Even despite fortification, infants fed breast milk after NICU discharge appear to have slower growth, different body composition, and less mineral accretion as compared with formula fed infants. A small (n = 37) study[54] compared growth, body composition, and bone mineral content of preterm (mean birth weight 1.4 kg) infants fed standard term formula vs. fortified breast milk after discharge. Although weight, length and head circumference were similar, formula fed infants had lower fat mass compared with breast milk fed infants, which parallels findings in term infants. Formula fed infants also had substantially higher bone mineral content at 6 months (159 vs. 132 g), although not at 12 months. The ratio of bone mineral content to lean mass was similar between breast milk and formula fed infants, suggesting that greater mineral accretion paralleled greater growth of lean mass in the formula fed infants. Longer term outcomes were not reported. It remains unclear whether faster vs. slower linear growth, greater gain in fat vs. lean mass, and degree of early bone mineralization is optimal with respect to later adiposity, neurodevelopment, and bone health outcomes.

A unique consideration for post-discharge fortification of breast milk

relates to the route of feeding. During most of the NICU hospitalization, fortified breast milk is administered by gavage tube. Once an infant is able to begin feeding orally by bottle or breast (typically around 34–35 weeks postmenstrual age and near the time of hospital discharge), the benefits of bottle feeding fortified milk must be weighed against the benefits of direct breastfeeding, since milk obtained by the infant directly at the breast cannot be fortified. Specifically, nutritional benefits of human milk fortification must considered alongside maternal preference for breastfeeding vs. bottle feeding and the logistical difficulties of expressing and fortifying milk, with the potential to reduce continued breastfeeding after NICU discharge.

Summary and Recommendations

Limited evidence supports the use of nutrient enriched formula for preterm infants after NICU discharge to improve early growth, and data are lacking with respect to long-term neurodevelopmental or cardiometabolic effects of such formulas. Typical in-hospital preterm formulas appear to support growth better than “transitional” or post-discharge formulas, but are not available outside of the hospital setting. Thus, standard practice is to discharge formula-fed infants on a post-discharge formula for several months to provide extra energy, protein, and minerals to support catch up in linear growth. Evidence from small studies suggests that fortifying human milk feedings after NICU discharge may improve both growth and neurodevelopment. A combination of direct feeding at the breast and bottle feeding of expressed and fortified milk may promote adequate growth while minimizing logistical barriers to continued breastfeeding. Clinicians should monitor growth with special attention to infants with rapid weight gain out of proportion to linear growth, which should prompt a decrease in caloric supplementation.

BREASTFEEDING AFTER NICU DISCHARGE

Continued breastfeeding of preterm infants after NICU discharge depends first on successful establishment of breastfeeding during the NICU hospitalization. In the United States, as compared with women who deliver at term, women who deliver preterm (<34 weeks’ gestation) are more than twice as likely to initiate breastfeeding and continue breastfeeding to 4 weeks. However by 10 weeks, women who deliver preterm are half as likely to breastfeed,[55] suggesting that while practices to support breast milk expression and feeding in the NICU are at least partially successful,

barriers after NICU discharge undermine continued breastfeeding.

Relatively recent data suggest that more than half of VLBW infants are still receiving at least some breast milk at NICU discharge. A California study[56] of 127 NICUs found that from 2005 to 2006, 61% of VLBW infants were fed breast milk at discharge, with wide variation noted across hospitals. Heavier infants and multiple births were more likely to receive breast milk at discharge, whereas younger women and those of racial and ethnic minorities were less likely to breast feed at discharge. An older (1999–2000) study[57] of 124 US NICUs found that approximately 50% of all NICU infants were receiving some breast milk at discharge, with similar inter-NICU differences and racial/ethnic and social disparities. National dataregarding breastfeeding continuation after NICU discharge are not available.

Despite early growth, bone, and neurodevelopmental advantages of post-discharge breast milk fortification, the process of expressing and fortifying milk itself may be a barrier to continued breastfeeding after NICU discharge. In the small randomized trial[51] of post-discharge breast milk fortification, breast milk intake was similar between fortified and unfortified groups at 12 weeks, but by 6 months, the experimental fortified infants had received less breast milk (33 vs. 71 mL/kg/d) vs. infants receiving unfortified milk. Total breastfeeding duration was also shorter for experimental infants (43 vs. 51 weeks). While greater lactation support during the intervention to 12 weeks is a possible explanation for these findings, another study found that simply providing additional lactation support does not appear to improve post-discharge breastfeeding duration, at least among highly motivated and socioeconomically advantaged populations.[58] Further research is needed to identify barriers to continued breastfeeding after NICU discharge.

Summary

Mothers who successfully initiate breastfeeding during the NICU hospitalization face challenges when continuing to breastfeed after discharge, including logistical barriers related to expressing and fortifying milk at home. Early lactation support may be helpful, but additional research is needed to identify strategies to improve duration and exclusivity of breastfeeding after NICU discharge.

SUMMARY

At the time of NICU discharge, the preterm infant faces substantial deficits in body size and nutrient accretion that must be addressed by strategies for nutritional support in the post-discharge period. Infants fed human milk may face greater deficits than formula-fed infants. Following NICU discharge, catch up in weight and length/height is complete by late infancy for many preterm infants, but for some continues through school age and late adolescence. A minority of preterm infants never fully catch up in weight and height to their term-born peers. More rapid post-discharge linear growth is associated with better neurodevelopment, but excess weight gain may lead to obesity-related complications later in life. Thus, the optimal pattern of post-discharge growth is unclear. Data from well-controlled randomized trials suggests that continued supplementation of energy, protein, and minerals after NICU discharge benefits short-term weight gain, linear growth, and possibly head growth, although evidence is stronger in support of formulas typically used during the NICU hospitalization rather than typical post-discharge formulas. Infants fed human milk after NICU discharge may benefit from at least partial milk fortification in combination with direct breastfeeding. Further research is needed regarding optimal nutrient supplementation in the post-discharge period, including a focus long-term growth, neurodevelopment, and cardiometabolic outcomes.

The Term Infant

34

Ekhard E. Ziegler, MD and Susan J. Carlson, MMSc, RD

THE GOALS OF INFANT FEEDING

The goals of infant feeding are to meet all nutritional needs, to aid mother-infant bonding, to aid the infant in making the transition from the predominantly liquid diet of the infant to the predominantly solid food diet of the child and adult, and to aid in establishing habits of eating in moderation. The goals can best be met by breastfeeding. However, in industrialized countries, feeding of commercially available infant formulas, although not ideal, is an acceptable substitute. Breastfeeding, besides meeting all nutritional needs, offers protection against infectious illnesses, may foster optimal neurocognitive development and may offer some protection against conditions in adulthood such as obesity and atherosclerosis. Whether feeding practices during infancy can aid in establishing the goal of eating in moderation is unknown. Nevertheless, in various animal models habits established during infancy have been difficult to extinguish later in life and it therefore seems reasonable that habits of eating in moderation should be established during infancy because they may facilitate eating in moderation later in life.

TRENDS IN INFANT FEEDING

The description of trends presented here chronicles events as they occurred in the United States. As infant feeding evolved in generally similar fashion throughout the industrialized world, the trends presented here are presumed to be representative of trends in most industrialized countries.

Historically, in situations where breastfeeding was not possible, survival of the infant was in jeopardy. The feeding of preparations based

on various mammalian milks was associated with high morbidity and mortality. Success at formula feeding gradually improved from the end of the nineteenth century through the first half of the twentieth century. The objective was to make available safe and effective feedings for situations where breast milk was not available. By the 1950s, formulas reached a point where they provided adequate nutrition and appeared to be reasonably safe. In the absence of convincing evidence of the inferiority of formula feeding, many parents and physicians adopted formula feeding, presumably because of the supposed greater convenience. The prevalence of formula feeding increased and the prevalence of breastfeeding decreased.

The decrease in the prevalence of breastfeeding was associated with earlier introduction into the infant's diet of complementary foods and cow milk. By the end of the 1950s, feeding of complementary foods was common during the first 2 months of life. Whole or reduced-fat cow milk commonly replaced formula by 4–6 months of age and often even earlier.[1]

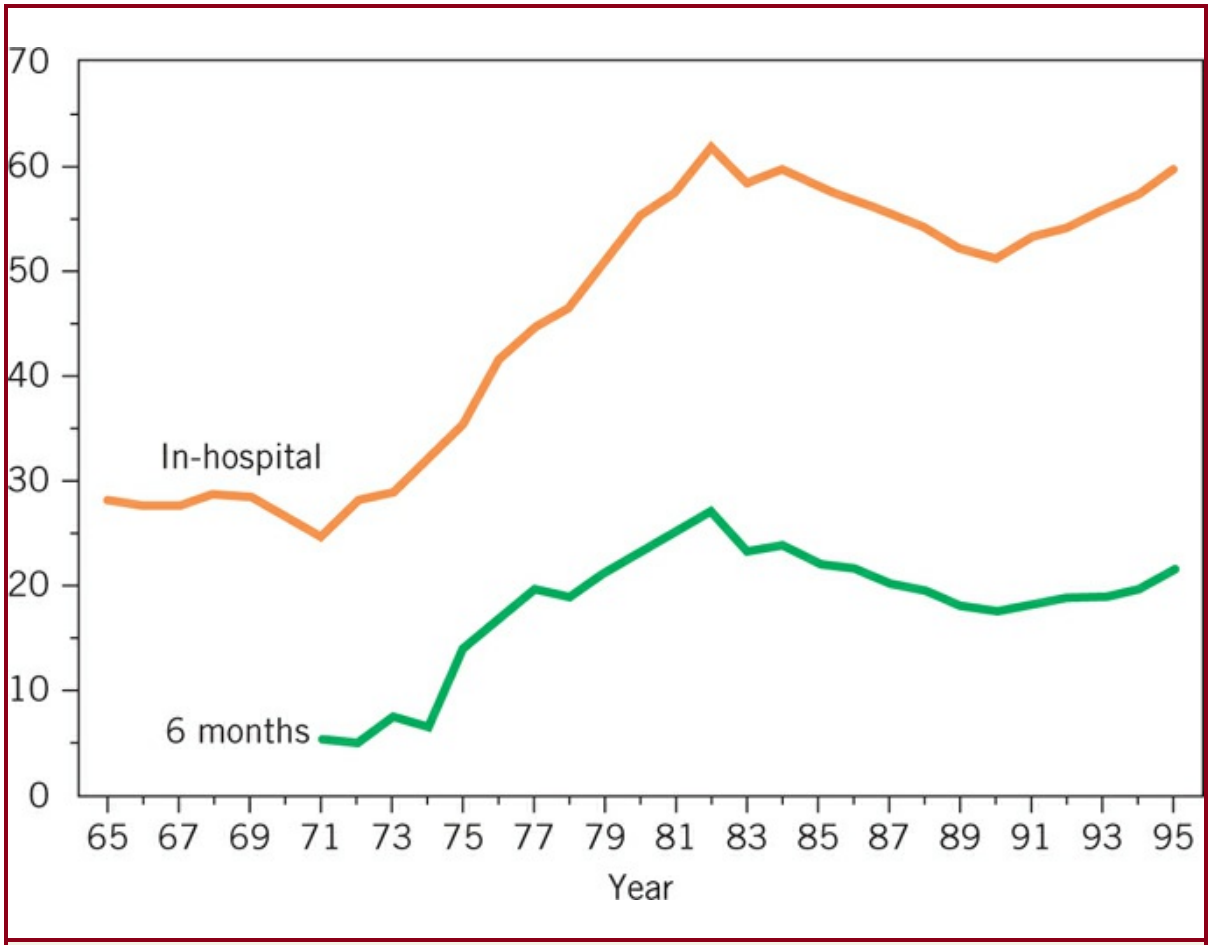

Figure 34-1 Prevalence of breastfeeding in the United States 1965-1995. Reproduced with permission from Ryan.[2]

A resurgence of breastfeeding began about 1971 (Figure 34-1). The reason(s) for the increase in breastfeeding are poorly understood. But enthusiasm for breastfeeding was sustained, at least in part, by the ever increasing number of reports on the demonstrated or assumed advantages of breastfeeding. As Figure 34-2 indicates, in 2001 about 70% of infants in the United States were breastfed for at least some time. That percentage increased to 83% by 2005–2007.[3] The relatively quick decrease in breastfeeding prevalence with age is at least partially explained by mothers returning to work. Despite the pressures of work, the number of women who breastfeed for six months and longer has continued to increase in the United States and reached 50% in 2005–2007.[3]

In association with the increase in breastfeeding, infants were increasingly fed formula after cessation of breastfeeding. Thus, formula feeding largely displaced feeding of cow milk in older infants except during the very end of the first year of life (Figure 34-3), a practice that seems to have persisted.[3] Also, complementary foods were less commonly fed during the early months of life. In 2005–2007, about 40% of mothers introduced complementary foods before 4 months.[4]

Trends in Formula Composition

The formulas fed in the United States in the late 1920s were generally prepared in the home from evaporated milk or fresh cow milk and sugar. The protein content was considerably greater than that of current formulas, the fat was butterfat, the added carbohydrate was corn syrup or sucrose and neither vitamins nor minerals were added. Prepared powdered formulas (to be diluted with water before use) were available but their use was quite limited until the 1950s. Over the years, formulas underwent a number of changes: the protein content was decreased and bovine whey proteins were included to result in a whey protein-casein ratio more like that of human milk; vegetable oils replaced butterfat; the added carbohydrate was lactose rather than corn syrup, and vitamins and minerals were included. See Appendix C for detailed composition of currently available formulas.

NUTRIENT REQUIREMENTS

The approach to estimating nutrient requirements of the infant differs considerably from that for adults. The normal adult requires regular intake of energy and specific nutrients to maintain the size and composition of the

body (i.e., requirements for “maintenance”), whereas infants and young children need, in addition, energy and nutrients for growth. The ratio of need for growth to need for maintenance is greatest for the fetus, the rapidly growing preterm infant and the term infant during the early months of life. Therefore, to obtain reasonable estimates of the requirements for energy and nutrients of the infant, it is desirable to have quantitative data on the increments in energy storage and the increments in specific nutrients needed for synthesis of new tissue. Defining the requirements of energy or nutrients for growth is much less important for children over the age of two years and for adolescents because by then the requirements for growth are quite small fractions of total requirements.

Thus, from a nutritional point of view, rapid growth is what differentiates infancy from all other ages. Nutrient requirements are exceedingly high primarily because nutrients are needed to support rapid growth. But growth is not only very rapid, it also changes dramatically in velocity as well as in composition. These dynamic changes are illustrated in Figure 34-4, which depicts rate as well as composition of growth of a “reference infant”. The rapid decline in the rate of growth during the first year of life is readily appreciated. It is also evident that during the first four months of life, infants deposit large amounts of body fat. During that period, fat accounts for as much as 40% of weight gain, and the energy necessary for deposition of this fat accounts for about 20% of energy requirements. Toward the end of the first year of life, fat deposition slows down markedly, and so does the proportion of energy requirement explained by fat deposition. Although accretion of protein as a percentage of weight gain increases with age, absolute protein accretion is highest during the first two months of life.

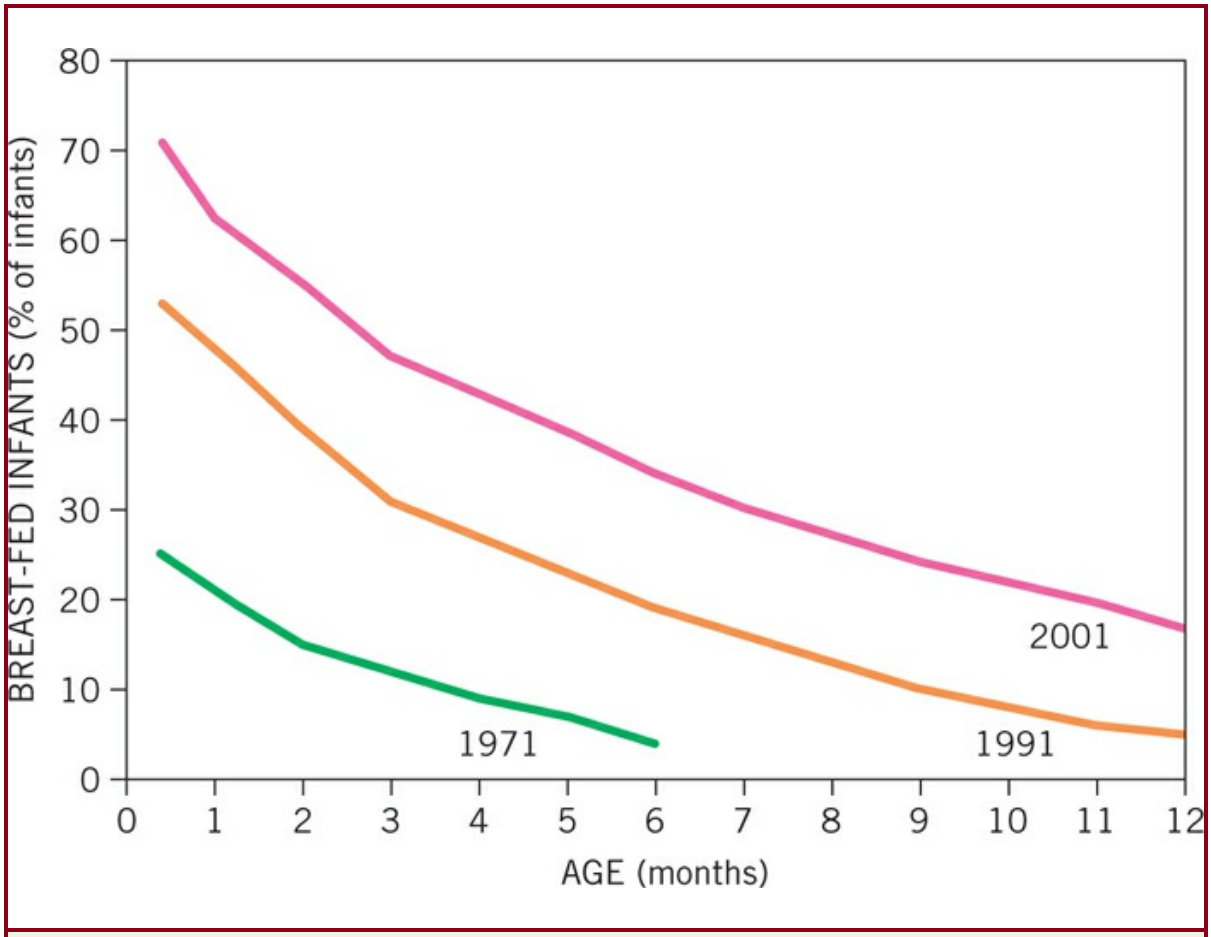

Figure 34-2 Exclusively and partially breastfed infants as a percentage of all infants in 1971, 1991, and 2001.

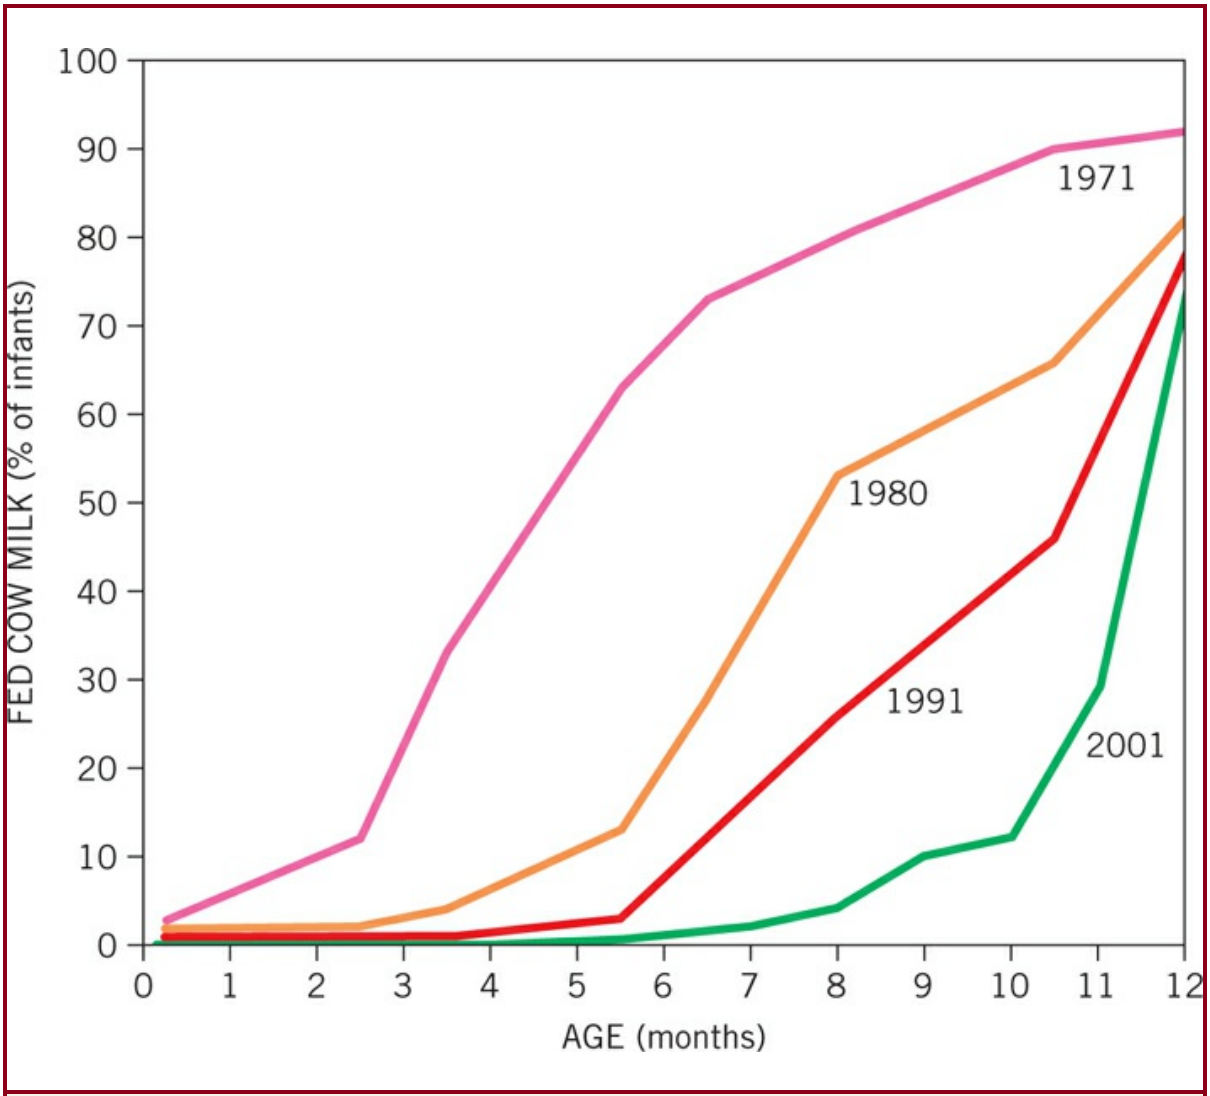

Figure 34-3 Infants fed cow milk (no breastfeeding, no formula feeding) as percent of all infants in 1971, 1980, 1991, and 2001.

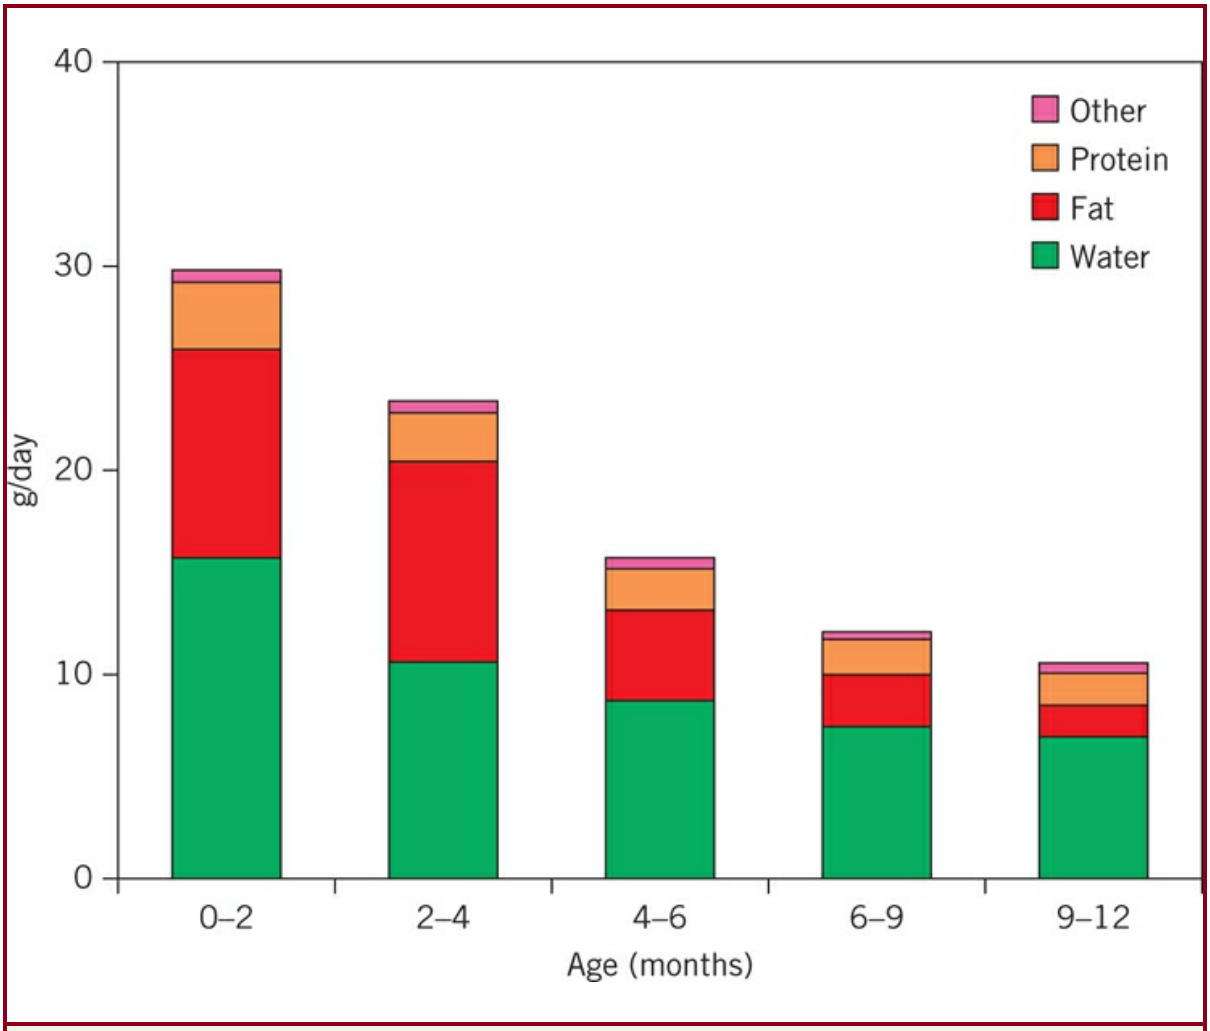

Figure 34-4 Gain in weight and in major body components of a "reference infant" (an infant with weight and length and body composition at the 50th centile for age). Based on Fomon and Nelson.[5]

Nutrient requirements of infants are obtained chiefly by two methods: The observational method and the factorial method. Each approach has its difficulties and limitations. The *observational method* relies on the model of the breastfed infant. The main difficulty with this approach is the determination of representative concentrations of nutrients in breast milk. Concentrations of many nutrients change markedly with the duration of lactation and are in many cases influenced by maternal dietary intakes. Also, the breastfed infant is not a reliable model in the case of certain nutrients, for example, iron, that are not provided in breast milk in amounts that meet the infant's needs. The *factorial method* yields good estimates for certain nutrients, such as protein, for which estimates of rates of accretion by the infant are available. Nutrient requirements, largely

because of the dynamic changes of the needs for growth, are strongly age dependent. Stating nutrient requirements in relation to energy requirements diminishes the age dependency of nutrient requirements some what, but does not eliminate it completely.

Energy Requirement

Because the infant possesses the ability to self-regulate energy intake, it may be assumed that energy intakes observed in infants receiving feedings with normal energy density represent energy requirements. Table 34-1 presents energy intakes observed in breast-fed and formula-fed infants. The data illustrate the markedly higher energy intakes during the early months of life compared to later infancy, a reflection of the deposition of large amounts of fat as energy stores. The data also show that formula-fed infants consume some what more energy than breast-fed infants, especially during the first three months of life. Therein may lie (part of) the reason for the somewhat more rapid growth of formula-fed infants. Gender-related differences in energy intake, although quite small, are nevertheless consistently present.

Protein Requirement

Table 34-2 presents estimates of requirements for protein by the factorial method as well as protein intakes observed in breast-fed infants. The close agreement between the factorial estimate and observed intake is striking. During the first month of life, growth accounts for over 50% of protein requirement. But by the end of the first year of life, the proportion needed for growth is less than 20%. It must be mentioned that other estimates by the factorial method yield some what lower estimates of protein requirements, largely because of lower assumed inevitable losses (0.56 g/kg/d).[7]

THE BREASTFED INFANT

Prevalence

Breastfeeding practices vary considerably from country to country. Not only does the rate of initiation of breastfeeding vary, but there is also large variation in the duration of exclusive breastfeeding (age of introduction of complementary feedings) as well as in the duration of any breastfeeding.[8] Besides local customs, legislation regarding protected time off work is presumed to have a major effect on the prevalence of breastfeeding.

Energy and Protein Intakes

The breastfed infant receives water, energy and specific nutrients in amounts that meet the needs of the infant at all times, notwithstanding the fact that the needs change with age of the infant. A prime example is protein. Through a combination of a sharp decrease in protein concentration in the first few months of lactation and an increase in milk

volume, a close match between intake of protein and protein requirement is achieved (Table 34-2). In the case of energy, whose content in breast milk does not change with the duration of lactation, the match between intake and need (Table 34-1) is achieved solely through a decrease in volume of milk consumed per kilogram of body weight. Most other nutrients fall somewhere between protein and energy, that is, a match between intake and need is brought about through a combination of concentration changes and volume increase. Formulas, on the other hand, must be designed to meet the highest possible needs, that is, those of the youngest infants in the target age group. Consequently, as the infant grows, nutrient intakes from formulas exceed needs by an increasing margin.

Although it is well established that infants generally do not obtain all the milk that is synthesized by the mammary gland, the cause of the failure to consume all the available milk is not known. One possible reason is infant fatigue since the process of obtaining milk from the breast requires considerable effort on the part of the infant. Whatever the mechanism may be, failure to consume all available milk may be one of the reasons why breast-fed infants consistently consume less energy than formula-fed infants, as shown in Table 34-1. It has been surmised that because the milk remaining in the breast is not visible to the mother, contrary to formula remaining in the bottle, she may be more prone to stop feeding at the earliest sign of satiety on the part of the infant than if the infant is fed by bottle.

Growth

Formula-fed infants grow more rapidly than breastfed infants. Differences in energy consumption may explain the difference in growth. However, inconsistent with this explanation is the fact that growth is similar during the first six weeks of life and only begins to differ significantly there after, whereas the difference in energy consumption seems to be largest during the first 2 months of life. Therefore, there may be other explanations. When the average intake is close to the average requirement for a nutrient, there is the likelihood that for some individuals intakes fall short of or exceed requirements. That is the case for protein (Table 34-2) and also for zinc, nutrients whose deficient intake can limit growth. Thus, it is possible that moderately inadequate intakes of protein or zinc, or both, occur among breast-fed infants and explain the difference in growth. But it must be stressed that the reason for the growth differential is not actually known. By the same token, it is not known whether there are any long-

term consequences, beneficial or detrimental, due to the slower growth of breast-fed infants, or due to the lower nutrient intake that is causing it. Nevertheless, it is widely assumed that the long-term health advantages of the breastfed infant are brought about by slower growth, or by the lower nutrient intakes that cause growth to be slower.

Flavor

Breast milk contains a variety of flavoring substances derived from the maternal diet, and there is clear evidence that the infant recognizes flavors and responds to them.[9] Thus, in contrast to the formula-fed infant, the breast-fed infant is exposed to a variety of tastes from the earliest age. The nutritional significance of early exposure to flavor variety, perhaps even in the long-term, is that it leads to greater acceptance and apparent enjoyment of novel flavors later on.[9]

Oligosaccharides

Breast milk contains substantial amounts (5–12 g/L) of oligosaccharides, a complex group of substances derived from lactose.[10] These oligosaccharides share similarities with epithelial cell surface carbohydrates and adhesion molecules. They exert a number of important functions, from blocking the adhesion of bacteria to intestinal cell surfaces to being responsible for the predominance of Bifidobacteria in the colonic microflora of the breastfed infant. Consonant with these important functions is the fact that oligosaccharides are only minimally digested in the upper gastrointestinal tract and undergo fermentation in the colon, thereby accounting for much of the hydrogen gas that is exhaled by breastfed infants.

Iron

Most infants are born with generous iron stores that render them independent of an exogenous supply of iron for the first 5–6 months of life. Breast milk provides a small amount of highly bioavailable iron that allows the infant to absorb about 0.15 mg each day. Beginning when iron stores are exhausted around 5–6 months of age, the infant needs to absorb approximately 0.75 mg each day in order to avoid iron deficiency. Since breast milk provides only about 0.15 mg/d of absorbed iron, the infant must absorb about 0.6 mg/d from other sources. Except for meat, which provides a highly bioavailable form of iron (heme iron), the natural iron content of most complementary foods is low. Therefore, the breast-fed

infant can obtain an adequate intake of iron, besides meat, only from iron-fortified foods, such as infant cereals, or from medicinal iron. These sources of iron have been demonstrated to be effective in preventing iron deficiency during prolonged breastfeeding.[11] However, concerns about adverse effects of medicinal iron limit its use, leaving iron-fortified cereals as the main source of iron for the breast-fed infant.

Some infants are born with diminished iron stores[11,12] and these infants may become dependent on an exogenous iron supply sooner than infants born with more generous iron stores. Because these infants may be prone to developing iron deficiency at a young age and thus be particularly vulnerable to the adverse effects of iron deficiency, it is advisable to start ensuring an adequate iron intake for all infants beginning at 4 months of age.

FORMULAS

Formulas provide macronutrients and micronutrients in amounts and proportions that permit infants to grow normally. Like breast milk, formulas provide energy in roughly equal amounts from carbohydrate and fat. Contrary to breast milk, the protein level is fixed and set at a level that meets the needs of the fastest-growing infants within the target age group. Formulas provide water in amounts that allow the infant to dispose of waste products with a satisfactory margin of safety. Owing to the higher potential renal solute load of formulas, that margin is somewhat narrower than in the breast-fed infant, a difference that is not known to be of clinical consequence.

An enumeration of the myriad substances that are provided by breast milk but are absent from formulas is beyond the scope of this chapter. A number of substances, including macro minerals, trace minerals, and vitamins, are provided in formulas in greater concentration than in breast milk. Some substances that are believed to be biologically important for the infant are added to formulas in amounts similar to breast milk. Some formulas, notably the soy protein-based formulas, provide substances that are not provided by breast milk. Of considerable nutritional importance is the presence of phytate because of its potential to inhibit the absorption of macro minerals and, especially, trace minerals. A group of substances collectively referred to as phytoestrogens is contained in soy formulas. These substances are not nutritionally important but are biologically active, exerting estrogenic as well as anti-estrogenic activities. Phytoestrogens are readily absorbed by the infant but produce no clinically

or otherwise recognizable effects. When followed into young adulthood, women who had been exposed to soy-formulas as infants had somewhat greater menstrual flow and experienced more discomfort with menstruation.[13] Although these effects are not known to be clinically important, they are biologically significant because they demonstrate that relatively brief exposure during a susceptible period can have effects that last for decades.

Nutrients

Carbohydrates

Milk-based formulas currently contain lactose as the sole carbohydrate and lack the complex mix of oligosaccharides that make up a substantial proportion of the carbohydrate of breast milk. Some formulas, however, contain longer-chain oligosaccharides, such as fructo-oligosaccharides, that exert prebiotic effects similar to those of human milk oligosaccharides. Human milk oligosaccharides are responsible for the differences in colonic flora between breast-fed and formula-fed infants. They are essentially nonabsorbable in the upper gastrointestinal tract, but the colonic micro flora is quite effective in fermenting them. The fermentation products, acetate and butyrate, are absorbed from the colon.

Fat

The fat of formulas is made up of various combinations of plant oils, selected to provide major fatty acids in approximately the proportions found in breast milk. The absorbability of the fat of formulas is similar to that of breast milk fat. Some formulas contain added long-chain polyunsaturated fatty acids (LC-PUFAs) (arachidonic acid [ARA] and docosahexaenoic acid [DHA]) in amounts similar to those present in breast milk.

Protein

Although formulas provide bulk casein and whey proteins in approximately the same proportions as breast milk, the individual whey proteins show little resemblance to those provided in breast milk. Manufacturers are able to selectively decrease and/or increase individual whey proteins and thereby alter the biologic quality and amino acid composition of the protein mix. The protein concentration of formulas is set to meet the highest needs, that is, those of the youngest infants in the

target age group. Consequently, older infants in the target group, who have lower protein needs than the younger infants, receive protein intakes that exceed their needs by some margin. In contrast, breastfed infants receive protein intakes that approximately match their needs at all times.

Iron

Formulas fortified with quite large amounts of iron (1.8 mg/100 kcal) were introduced in 1959 and were shown to be effective in preventing iron deficiency. Although non-iron-fortified formulas continued to be used, the use of formulas providing iron at 1.8 mg/100 kcal gradually increased, and in the year 2001 they accounted for about 95% of formula sales. At present, all routine formulas contain added iron at 1.8 mg/100 kcal. Iron fortification is not associated with adverse effects on gastrointestinal function.

Formula Composition

Compositional standards for routine formulas and formulas for special medical purposes are laid down in the Codex alimentarius.[14] Formulas for *routine use* are rather uniform in composition, as is evident from Table C-1 of Appendix C. Some formulas provide partially hydrolyzed whey proteins. The latter type of formula is sometimes referred to as "hypoallergenic".

A number of formulas are available that contain *no lactose*. Their composition is also shown in Table C-1, Appendix C. While those based on soy protein isolate (with methionine supplementation) have been available for many years, those based on cow milk have been introduced more recently. Although the scientific basis for the widespread use of these formulas is uncertain, it can be said that these formulas provide all essential nutrients and support normal growth. The carbohydrates that are provided in lieu of lactose include sucrose and fractions of corn syrup. The protein concentration of soy-based formulas is generally higher than that of milk-based formulas, reflecting the (presumed) somewhat lesser quality (per unit of weight) of methionine-supplemented isolated soy protein. Although all lactose-free soy-based formulas contain iron at 1.8 mg/100 kcal, this includes a substantial amount of iron provided by the soy protein isolate. Little is known about the bioavailability of this iron.

Table C-1 also lists the *extensively hydrolyzed formulas* (also referred to as predigested) and *elemental formulas*. These formulas are characterized by the absence of intact protein as well as lactose. The source of nitrogen is hydrolyzed casein or hydrolyzed whey proteins, and

in the case of elemental formulas, free amino acids. Three of the formulas provide a sizable proportion of their fat in the form of medium-chain triglycerides. Formulas designed for *specific medical indications* include formulas that are of thicker than usual consistency and are intended for infants with severe gastroesophageal reflux. Some special formulas are intended for infants recovering from diarrhea. A formula with low sodium and phosphorus content is used in infants with renal failure.

Substances Added to Formulas

Of the many bioactive substances that are present in human milk but are contained in cow milk in lower concentration or are completely absent from cow milk, some are added to formulas. Evidence that the addition ameliorates an otherwise existing deficiency is not always very convincing. However, it appears reasonable to add a substance when its presence in breast milk seems “intentional” and when its absence from the infant’s diet is associated with deficits in serum or tissue concentrations relative to the breast-fed infant. A prerequisite for the addition of any substance is, of course, the availability of the technology necessary for making the addition feasible. The list of substances added to formulas now includes taurine, carnitine, nucleotides, lutein, and long-chain polyunsaturated fatty acids.

Taurine

Taurine is an amino sulfonic acid found in high concentration in certain parts of the developing brain and in the retina. In infants taurine also plays a role in the conjugation of bile acids and it has osmoregulatory functions. Taurine is synthesized from cysteine and the term infant (but perhaps not the preterm infant) appears to possess ample capacity to carry out the conversion. Breast milk contains appreciable quantities of taurine, whereas the taurine content of cow milk and hence of cow milk-based formulas is only a fraction of that of breast milk. However, except for low plasma taurine concentrations, adverse effects due to low taurine intakes have not been demonstrated convincingly. Nevertheless, all formulas contain added taurine.

Carnitine

Carnitine plays an essential role in the entry of fatty acids into the mitochondria and hence is necessary for fatty acid oxidation. Carnitine is derived from endogenous synthesis as well as the diet. Breast milk, cow milk and hence milk-based formulas, and meat provide ample amounts of

carnitine. When carnitine is absent from the diet, plasma concentrations of infants are low and certain biochemical abnormalities are observed, whose clinical significance is uncertain. Carnitine is added to all formulas.

Nucleotides

Breast milk contains free RNA nucleosides (adenine, cytosine, guanine, and uridine) as well as their respective nucleotides (i.e., nucleosides with one sugar moiety and one or more phosphate groups attached), and some polymeric RNA. The amount of nucleosides in breast milk is considerably higher than in cow milk. It is thought that during times of high demand, that is, during rapid growth, dietary nucleosides are useful and may be conditionally essential. Animal studies have shown nucleosides to enhance T-cell function and gastrointestinal maturation. Fortification of infant formula with the four main nucleotides found in human milk led to enhanced antibody responses to *H. influenzae* type b and diphtheria.

Lutein

Lutein is a carotenoid and like other carotenoids has anti-oxidant and anti-inflammatory properties. It is highly concentrated in the macula area of the retina. It is contained in breast milk and is added to some formulas.

LC-PUFAs

These fatty acids have received considerable attention in recent years. Although the consequences, especially those in the long term, of a lack of these fatty acids in the infant's diet remain controversial, formula manufacturers are now offering many formulas with and without added LC-PUFAs. Formulas with added LC-PUFAs are specially designated. The fatty acids in question are DHA and ARA. DHA is a C22 n-3 fatty acid with six double bonds. It is derived from dietary α-linolenic acid by a series of chain elongation and desaturation steps. ARA is a C20 n-6 fatty acid with four double bonds. It is derived from dietary linoleic acid. Breast milk contains preformed DHA (about 0.2% of fatty acids) and ARA (about 0.5% of fatty acids). The plant oils used in manufacturing formulas do not contain DHA and ARA and formulas are devoid of DHA and ARA unless these fatty acids are specifically added from other sources.

Infants, including premature infants, have the ability to synthesize DHA and ARA from their respective precursors, but the synthetic capacity appears to be insufficient to keep up with the high demands for growth. DHA is needed for incorporation into cortical gray matter and the retina. In infants who are fed formulas devoid of DHA, concentrations in gray

matter and retina are substantially lower than in breast-fed infants.[15] The same is true for concentrations in plasma and erythrocyte membrane lipids. Infants fed DHA-free formulas show evidence of impaired retinal function during the early months of life. However, this effect seems to be transient and is no longer demonstrable in older infants. The presence of DHA and ARA in formulas is considered desirable because these fatty acids are present in breast milk and because their absence from the infant's diet produces abnormal concentrations in brain, retina, erythrocytes, and plasma.

WEANING AND COMPLEMENTARY FOODS

Weaning is the withdrawal or displacement of breastfeeding. The weaning period begins with the first introduction of a food other than breast milk (water and vitamin-mineral supplements are not considered to be food) and extends until the complete discontinuation of breastfeeding. We do not apply the term weaning to the withdrawal and displacement of formula. Solid and semi-solid foods that are fed in addition to breastfeeding are referred to as complementary foods or weaning foods.

Age of Introduction of Complementary Foods

Evidence that infants can tolerate complementary foods before the currently recommended age of its introduction was provided by the experience in the 1950s and 1960s, when various complementary foods were fed to many infants even during the early weeks of life without any apparent ill effects.[1] One reason for deferring the introduction of complementary foods to 4–6 months of age is that the infant acquires around 4 months the ability to sit with support and have adequate neuromuscular control of trunk and neck. But another reason is that complementary foods are thought to interfere with the immune-protective effects of breastfeeding. This is the main reason why the WHO in 2003[16] recommended that exclusive breastfeeding should continue to six months and that complementary foods should therefore be introduced after six months. Some professional organizations, such as the American Academy of Pediatrics,[17] have endorsed the WHO recommendation, citing evidence that exclusive breastfeeding even in developed countries provides better protection against diarrhea and lower respiratory disease[18,19] than mixed feeding (breastfeeding plus complementary foods). There is also the possibility of long-term benefits such as protection against obesity later in

life.[20] Other organizations[21,22] and individuals[23] have argued that the evidence favoring exclusive breastfeeding for six months is weak and that the absence of complementary foods places the breastfed infant at risk of micronutrient deficiency, for which there is some evidence in the case of iron.[24,25] From the point of view of allergy prevention, it seems that introduction of complementary foods between four and six months is preferable over earlier or later introduction.[21] Weighing infectious morbidity risk against the risk of iron deficiency, the authors favor introduction of complementary foods between four and six months.

Choices of Complementary Foods

There is no evidence that the sequence of introduction of various complementary food items is a matter of great importance. It is convenient to begin with cereal because a small amount of the dry powder can be mixed with breast milk or formula at quite low expense. Initially, only a small amount, less than a teaspoonful, should be given at one time. Whether pureed fruits or vegetables are then introduced seems of little consequence. However, single foods rather than combinations should be offered. It is generally recommended that one food be fed for several days before introducing another. It is desirable to work toward acceptance of variations in tastes and textures.

The exclusively breastfed infant consumes an adequate intake of protein but, once complementary food begins to comprise a substantial portion of the total energy intake, it is important to include some high protein foods. Deficiency of iron and zinc in breastfed infants is possible. Meats, especially red meats, are a good source of protein, zinc, and a highly bioavailable form of iron. We recommend for the breastfed infant that soft-cooked meats be introduced within the first month or two of complementary feeding (by 5 or 6 months of age). We consider the risk of iron and zinc deficiency to be greater than the risk of sensitization to meat proteins.

With the exception of providing sources of iron and zinc of high bioavailability for the breastfed infant, the goal of feeding complementary foods is to begin the transition from the infant's primarily liquid diet to the predominantly solid food diet of the child. Therefore, as infancy progresses, the variety of flavors and textures offered to the infant should gradually be increased.

Fruit juices should be fed sparingly and only by cup. Fruit juices are associated with adverse reactions and do not provide nutrients that are

lacking in the diet of the breastfed or formula-fed infant.

COW MILK

Feeding of cow milk during the first year of life is undesirable because such feeding is associated with the development of iron deficiency. It is unclear which of the several mechanisms is mainly accountable for the iron deficiency. It has long been recognized that ingestion of large quantities of cow milk may result in low intakes of other foods that contain more generous amounts of iron. In addition, there is considerable evidence that ingestion of cow milk causes occult gastrointestinal blood loss.[26] Finally, cow milk provides high intakes of casein and calcium, potent inhibitors of iron absorption that may contribute to the development of iron deficiency.

The potential renal solute load provided by cow milk is undesirably high.[27] Feeding of whole cow milk does not interfere with maintenance of water balance in normal infants under most circumstances. But in a hot environment or during febrile illness, especially if associated with decreased fluid intake, the infant is at greater risk of dehydration if fed cow milk than if breastfed or fed formula. The margin of safety is greater with breastfeeding or feeding of infant formulas than with feeding of cow milk.[27]

Complementary Feeding and Health Outcomes

Mary S. Fewtrell, MA, MD, FRCPCH

INTRODUCTION

Complementary foods are defined by the World Health organization (WHO) as any food or liquid other than breast milk.[1] They are required during the second part of the first year of life for both nutritional and developmental reasons, and to enable the transition from milk feeding to family foods. The ability of breast milk to meet macro and micronutrient requirements becomes limited at this point, whereas from a developmental perspective, infants develop the ability to chew and start to show an interest in foods other than milk.

Current recommendations on the age at which complementary foods should be introduced are based on consideration of the optimal duration of exclusive breast-feeding (EBF) in terms of nutritional adequacy and effects on health outcomes. Following a systematic review[2] and expert consultation in 2001, WHO recommended that all infants should be exclusively breast-fed for six months followed by the introduction of

complementary foods alongside continued breast-feeding.[3] However, because human milk substitutes (HMS; infant formulas and follow-on formulas) are defined by WHO as complementary foods, this definition can be confusing: in high-income countries where many infants receive HMS from the first weeks of life it is not clear whether recommendations based on the duration of EBF should apply to these infants with respect to the introduction of other nonmilk foods. In recent years, debate on the optimal age for introducing complementary foods in different situations has largely overshadowed discussion on the optimal content of the diet during this period, and the age at which specific foods should be introduced.

This chapter will discuss evidence for health effects of complementary feeding practices, considering timing, content, and feeding behavior, and will focus on infants in higher income countries. Nutritional considerations and issues for infants living in lower income settings are considered in Part V, Chapter 43.

TIMING OF COMPLEMENTARY FEEDING

Complementary feeding practices are strongly influenced by social and cultural factors, and vary markedly between countries. There is general agreement that complementary foods should not be given before 17 weeks of age, as early introduction may be associated with an increase in fatness, wheeze, and eczema later in childhood.[4] Recommendations for the age at which complementary foods should be introduced are generally based on infant developmental readiness, nutritional requirements, and the health effects of different practices. In terms of developmental readiness, gastrointestinal and renal functions are likely to be sufficiently mature by around 4 months of age to enable infants to process some complementary foods. With regard to neurodevelopmental readiness, it is probable that there is a range at which infants attain the necessary motor skills to cope safely with complementary foods, but these skills typically appear during the 4- to 6-month period. It is however important to recognize that the skills required will depend on the type of complementary foods that are to be introduced, and that the neurodevelopmental readiness required for an infant to safely accept and swallow pureed complementary foods from a spoon differs from that required to handle semisolids or to self-feed, as currently advocated in the “baby-led weaning” approach currently popular in some higher income countries (see below).

Scientific Evidence to Support Recommendations on the Duration of EBF and the Introduction of Solid Foods for Infants in Developed/High-Income Countries

It is important not to confuse evidence for the optimal duration of EBF with that for breast-feeding *per se*.[5] Current advice on the length of EBF is based on a global recommendation introduced by the WHO in 2001 following a systematic review and expert consultation on the health effects of EBF for six months compared to EBF for 3–4 months with continued partial breast-feeding alongside the introduction of complementary foods. This review did not address the introduction of solid foods in infants who are receiving infant formula (a significant proportion in many high-income countries for 5–6 months), since the latter is defined by the WHO as a complementary food. The review[2] initially included 16 eligible studies, seven of which were from developing countries. With the exception of two randomized trials in Honduras, all of the studies were observational and therefore subject to the many well-described methodological problems associated with this type of study,[6,7] notably confounding factors associated with the decision to introduce complementary food. An update of the systematic review was published in 2012, including a literature review to June 2011.[8] A total of 23 eligible studies were identified—11 (2 randomized) from developing countries and 12 (all observational) from developed countries. No new randomized trials had been conducted since the original review, and the conclusions were largely unaltered, with no new findings of relevance specifically to infants in developed countries. The review's main conclusions were that EBF for six months, compared with EBF for 3–4 months with partial breast-feeding thereafter, is associated with:

- a significantly reduced risk of gastroenteritis (studies from Belarus, Iran and Nigeria; adjusted odds ratio 0.61; 95% confidence interval 0.41–0.93 for infants in Belarus)
- no apparent growth deficits
- no apparent relation with the development of allergy
- poorer iron status for infants in developing country settings where newborn iron stores may be suboptimal: in the Honduras randomized trial, infants exclusively breast-fed for six (vs. four) months had lower mean hemoglobin (difference–5.00 g/L; 95% confidence interval–8.46 to –1.54), and ferritin concentrations
- delayed return of menses (studies from Honduras, Bangladesh, and Senegal) and more rapid postpartum weight loss in mothers

(Honduras)
- no effect on height, weight, body mass index (BMI), dental caries, cognitive ability, or behavior at 6.5 years (Belarus)

Thus, for infants in higher income countries, the most relevant health benefit demonstrated was a reduced risk of gastrointestinal infection in infants EBF for six months. This finding came from an observational analysis of data from the PROBIT study, a large cluster-randomized trial of a breast-feeding promotion intervention.[9] The protective benefit of EBF against gastrointestinal infection in this study was confined to the 3–6-month age period during which feeding practices differed between the two groups.

In a second systematic review, also published in 2001 but examining the health effects of the timing of introduction of solids in both breast-fed and formula-fed infants, Lanigan et al[10] identified 33 eligible studies, and concluded there was no compelling evidence to support changing from the existing recommendation to introduce solids at 4–6 months; in their opinion, 13 studies supported a change, 13 did not, and the remaining 7 did not provide evidence for either position.

In 2009, a review was commissioned by the European Union (EU) and conducted by an Expert panel for the Nutrition, Dietetics, and Allergy Committee of the European Food Safety Authority (EFSA), to address the issue of when complementary foods can be safely introduced into the diets of infant in the EU.[11] Their main conclusions were:

- As long as complementary feeding is introduced after four months of life it does not constitute a problem for the digestive system or the renal function of the infant.
- The age of introduction of complementary feeding seems not to have a strong impact on growth velocity.
- It is justified to assume that EBF by well-nourished mothers for six months can meet a healthy infant's need for energy, protein, and for most vitamins and minerals with the exception of iron and zinc, particularly in situations where the maternal diet is poor.
- Breast-feeding protects against infectious morbidity. This effect is proportional to the length of breast-feeding. The available evidence suggests that early introduction (<3 months) of complementary feeding may increase the risk of infectious morbidity. There seems to be no effect of introduction of complementary feeding after four months on the risk of infectious morbidity.

- There is no convincing scientific evidence that avoidance or delayed introduction of potentially allergenic foods reduces allergies in infants considered at increased risk for the development of allergy or in those not considered to be at increased risk. The available data do not permit a conclusion on the appropriate age for introduction of complementary feeding with respect to allergy prevention or reducing the risk of allergy.
- The available data suggest that gluten containing complementary feeding could be introduced after four months in small amounts preferably while the infant is still breast-fed.
- The age of introduction of complementary feeding seems not to have a clear impact on the risk of obesity.

Overall, the Panel concluded that the introduction of complementary food into the diet of healthy term infants in the EU between the age of 4 and 6 months is safe and does not pose a risk for adverse health effects. Following the publication of this opinion, the U.K. Department of Health requested an expert review and comment on the data relevant to the age at introduction of gluten. The conclusion,[12] based on a consideration of the same data examined by the EFSA panel, was that the evidence was not sufficient to support EFSA's conclusion on the introduction of gluten into the infant diet not later than 6 completed months of age with the aim of reducing the risk of subsequent development of coeliac disease and type 1 diabetes. This example of expert groups arriving at different conclusions based on the same available scientific evidence illustrates well the problem of developing recommendations when the data are subject to so many limitations.

A synthesis of available data on the health effects of six months EBF with a particular focus on infants in higher income countries is presented below, including studies that were not eligible for the Kramer systematic review. The discussion also includes some data published since the last update of the systematic review, notably results from the only randomized controlled trial to compare four versus six months EBF in infants living in a high-income country.

Infection

Five observational studies in developed countries have now provided evidence on the duration of EBF and risk of infection. Questionnaire based data from the National Health and Nutrition Examination Survey III cohort[13] showed that U.S. infants who were EBF for more than six months

had lower risk of pneumonia and recurrent otitis media than those breast-fed for 4–6 months. A Spanish study found the risk of hospital admission for all infant infections was decreased with longer EBF; although, this advantage was seen principally before three months, with little apparent benefit thereafter.[14] A German study[15] found infants exclusively breast-fed for six months, compared with less than four months, had less gastroenteritis. Duijts et al[16] reported that, compared with never-breast-fed infants, those who were breast-fed exclusively until the age of 4 months and partially thereafter had lower risks of upper and lower respiratory tract and gastrointestinal infections until the age of 6 months and of lower respiratory tract infections between the ages of 7 and 12 months. Similar tendencies were observed for infants who were exclusively breast-fed for six months or longer, whereas partial breast-feeding, even for six months, did not result in significantly lower risks of these infections. Finally, the large U.K. Millennium cohort study suggested that 53% of admissions for gastroenteritis and 27% of those for chest infection could be prevented each month by EBF, with a smaller protective effect from partial breast-feeding.[17] Importantly for practice, in subsequent analyses, it was shown that it was the introduction of infant formula, not solid foods, that predicted an increased likelihood of hospital admission.[18]

Nutritional Adequacy

An important issue is whether EBF for six months feeding reliably supports adequate growth—traditionally used as a measure of overall nutritional status. The Kramer systematic review[2,8] suggested no apparent growth deficits associated with six months EBF for infants in either developing or developed country settings, although with the caveat that data were insufficient to exclude small effects. However, because infants who are EBF for six months represent a minority in all settings, it is important to consider whether generalizing findings from this small and potentially biased subgroup to the whole infant population is appropriate. Reilly and Wells[19] conducted a systematic review of infant energy requirements, breast milk output, and energy content, and calculated that many mothers who exclusively breast-fed would not support their infant's energy requirements to six months. Subsequently, Neilsen et al[20] conducted an observational study measuring breast milk production and energy content noninvasively using stable isotopes in 47 British infants who were EBF for six months. Milk intakes were higher than published values and increased significantly between time points (923 (SD 122) g/d

at 15 weeks, 999 (SD 146) g/d at 25 weeks of age, mean increase 61 g/d (95% confidence interval: 23–99). Infant growth was normal using WHO Child Growth Standards, and energy intakes were adequate compared with reference requirements. Behavioral data also indicated no evidence of strain on breast-feeding practices. These results show that in mother–infant pairs who successfully EBF for six months, physiological adaptations occur in milk production to support normal infant growth. However, it is still not certain whether these findings can be generalized to the whole population since the mothers in this study were a small and highly selected —notably, well educated—subgroup.

Most recently, in the first randomized trial of the duration of EBF to be conducted in a high-income country, Wells et al[21] reported significantly higher breast milk intake at age 6 months in a cohort of 100 Icelandic infants randomized to six months versus four months EBF; breast milk intake was 83 g/d (95% CI: 19, 148 g/d) greater (mean ± SD: 901 ± 158 g/d vs. 818 ± 166 g/d), equivalent to 56 kcal/d. Infants who received complementary foods obtained 63 ± 52 kcal/d from these foods, suggesting complementary foods displaced breast milk in the early introduction group. Estimated total energy intakes were similar and anthropometric outcomes and body composition did not differ significantly between groups.

Another issue of uncertainty is whether six months EBF reliably meets infant iron requirements for infants in higher income settings. This is of concern given the association of iron deficiency anemia with adverse mental, motor, and psychosocial outcomes.[22,23] In the Icelandic randomized trial comparing four versus six months EBF, infants in the six month group had significantly lower serum ferritin at age 6 months[24] although the proportion of infants with iron deficiency, anemia, or iron deficiency anemia did not differ in this small study. Although this finding suggests a positive effect of earlier introduction of solids on iron stores, even in a population considered at fairly low risk of iron deficiency, the biological significance of the findings is uncertain. Two observational studies from the United States[25] and Germany[26] have also reported poorer iron status in infants EBF for six months versus those EBF for shorter periods or formula-fed. In countries where there is no routine screening for iron deficiency it would currently be impossible to detect such adverse effects.

It is important to emphasize that there are a number of potential methods for avoiding poor infant iron status other than introducing iron-rich solid foods, including delayed clamping of the umbilical cord—which

has proven efficacy and safety even in Swedish infants considered at low risk for iron deficiency[27]—and iron supplementation of infants. However, these methods are unlikely to be systematically implemented without recognition of the issue and a specific action plan.

Allergy and Coeliac Disease

The Kramer systematic review did not find a link between EBF duration and allergic disease. However, this is an area of ongoing research and discussion. Paradoxically, many developed countries have rising rates of food allergy, despite increasing advice to restrict and delay exposure to potentially allergenic foods, including cows' milk, egg, fish, gluten, peanut, and seeds. Moreover, countries where peanuts are commonly used as weaning foods, such as Israel[28] have low incidences of peanut allergy. These observations have prompted further research on immune tolerance to foods. It has been proposed that the development of immune tolerance to an antigen may require repeated exposure, perhaps during a critical early window, and perhaps modulated by other dietary factors including breast-feeding. A 2008 review[29] reported an increased risk of allergy if solids were introduced before 3–4 months. After four months, the evidence was weak, but suggested an increased risk with delayed introduction of certain allergens. Recently, Nwaru et al[30] reported data from a large Finnish cohort (n = 3781) investigating associations between the duration of breast-feeding and timing of introduction of complementary foods and the development of asthma and allergies by the age of 5 years. They concluded that a longer total duration of breast-feeding rather than its exclusivity was protective against nonatopic asthma, whereas earlier introduction of certain allergenic foods (wheat, rye, oats, and barley cereals at 5.5 months or less; fish at 9 months or less; and egg at 11 months or less) was associated with a decreased risk of asthma, allergic rhinitis, and atopic sensitization in childhood; these findings were unchanged by adjustment for confounders and for potential reverse causality.

Two randomized trials in the United Kingdom are currently investigating the hypothesis that the earlier introduction of allergenic foods may reduce the subsequent risk of allergy: the Learning Early About Peanut Allergy study which addresses the timing of exposure to peanuts in high risk infants, and the Enquiring About Tolerance study which is investigating early (from three to four months) versus delayed (beyond six months) introduction of six potentially allergenic foods in a general

population of infants, not selected for risk of atopy. Data from these studies will add significantly to the evidence base.

The specific issue of the relationship between the introduction of gluten-containing cereals and subsequent development of celiac disease has been much studied, particularly in Sweden where the incidence of early onset coeliac disease increased following advice to delay introduction of gluten until age 6 months, and fell to previous levels after the recommendation reverted to four months. Subsequent analyses suggest that gluten should ideally be introduced in small quantities alongside continued breast-feeding and these data are generally more robust than data on the *timing* of introduction.[31] Based on this, and other observational studies, many expert groups have suggested it is prudent to advise mothers to introduce gluten at a time when they are still predominantly breast-feeding (supported by the ESPGHAN CoN[32] and the AAP[33]). However, the recent publication of two randomized trials reporting that neither the timing of introduction of gluten or breastfeeding influenced the proportion of infants who went on to develop celiac disease[34,35] may lead to reappraisal of this advice; and also illustrates the limitations of observational data as a basis for practice.

Longer Term Health Outcomes

There are limited data on later health outcomes in relation to the duration of EBF or the age at introduction of solid foods. In Scottish infants, the introduction of solids before 3–4 months was associated with increased fatness, wheeze, and eczema at age 7 years.[1] A 6.5-year follow-up of the Belarus PROBIT cohort[36] showed no effect of EBF for six months versus three months on blood pressure, cognition, atopy, and dental caries. However, in a Danish birth cohort[37] earlier introduction of solids was associated with late emergence of a higher risk of overweight at 42 years. A recent systematic review examining the association between the timing of complementary feeding and risk of obesity in infancy and childhood[38] identified 24 studies that met the inclusion criteria, providing data from over 34,000 participants for interpretative analysis. No clear association between the age of introduction of solid foods and obesity was found.

Balance of Risks and Benefits

Data on the health effects of the timing of introduction of complementary feeding for infants in high-income countries suggest there may be a balance of risks and benefits. Clearly for infants living in situations where

there is limited access to clean water or safe, nutritious complementary foods, with significant risk of morbidity and mortality from infectious diseases, the protective effect of more prolonged EBF would override any other considerations. Available data suggest that more prolonged EBF also protects against gastrointestinal and respiratory infection, and hospitalization for such infections, in infants living in higher income settings. However, more prolonged EBF may not be nutritionally optimal for all infants, particularly for iron, and delayed introduction of certain allergenic foods, especially at the point where breast-feeding has decreased or ceased, may be associated with increased risk of allergy. Hence, the risks and benefits should be considered in each setting. Perhaps the most urgent requirement in this field is for new data, preferably, as suggested by Kramer and Kakuma,[2] from randomized trials, although these are difficult to conduct in practice especially given strong opinions on the topic which make it difficult to identify suitable subjects and investigators.

CONTENT OF THE COMPLEMENTARY FEEDING DIET

Most current guidelines for the gradual introduction of different foods during the complementary feeding period are based on cultural factors and food availability rather than scientific evidence. Although in developing countries the focus is still predominantly on providing adequate nutrients to support growth and development (see Part V, Chapter 43), in more affluent environments achieving a better balance of nutrients and avoiding excess may be more important. Nutritional recommendations for the complementary feeding period are based on the concept that breast milk will not meet full requirements for energy, protein, and micronutrients beyond about 6 months of age and assume that complementary foods are combined with breast milk; but this is not the case for a significant proportion of infants in many high-income countries. Deriving appropriate population-based recommendations for intakes of specific nutrients or foods is problematic in the situation where the nutrient intake from milk varies significantly between infants depending on the type of milk they are consuming. For example, the iron intake from breast milk, infant formula, and cow milk varies markedly with the consequence that it is almost impossible to define an “average” requirement that is required from complementary foods. For this reason, it is important to consider infant diets on an individual basis, taking into account the main source of milk. Theoretically, the requirement for good quality complementary foods—

particularly those rich in iron and zinc—may be more important for breast-fed infants, since an infant fed entirely on HMS will have higher intakes of these nutrients from milk at this point. In practice, however, most authorities consider it undesirable and impractical to have different recommendations for breast-fed and formula-fed infants.[32]

Specific Nutrients or Foods

Energy

Energy requirements remain high throughout the whole of the first year of life. The fat content of the diet is an important determinant of its energy density; it should not be less than 25% of energy intake and a higher proportion may be required if the infant has a poor appetite, recurrent infections, or is fed infrequently. It is generally advised that reduced fat cow's milk and other low fat products should not be introduced too early as this will reduce the energy density of the diet. However, consideration should be given to the rest of the infant's diet, and to his or her growth. In countries with high rates of child obesity, it may be advantageous to accustom children to low-fat products from a fairly early age. The Finnish STRIP study, a large ($n > 1000$) trial in which the intervention group were given dietary advice to reduce the intake of saturated fats from infancy throughout childhood has reported beneficial effects on plasma lipid profile and endothelial function, particularly in boys, with no adverse effects on growth to age 14 years or on cognitive development at age 5 years. The intervention resulted primarily in changes in dietary fat quality rather than quantity and also resulted in the consumption of generally healthier diets later in childhood.[35]

Iron and Zinc

More than 90% of iron requirements during the complementary feeding period in a breast-fed infant must be provided by complementary foods. Potential strategies for achieving this include the use of fortified weaning foods, iron-fortified infant formulas and follow-on formulas, foods naturally rich in bioavailable iron such as meat, or the use of supplements. The most suitable strategy or combination of strategies will vary in different circumstances and, as discussed above, the iron needed from complementary foods will depend on the infant's main source of milk since infant formulas and follow-on formulas are supplemented.

Cow milk is a very poor source of iron, and it is generally recommended that it should not be used as the main drink before 12

months of age.[32] In a prospective observational cohort of 928 British term infants, those consuming cow milk as the main drink had an increased incidence of anemia at 12 months and low serum ferritin at 8 and 12 months. More than 25% of infants having breast milk and cow milk as their main drink and 41% of infants having more than six breast feeds per day had iron intakes below the lower reference nutrient intake, whereas infants consuming more than 600 mL/d of cow milk or formula or taking more than six breast feeds per day had lower intakes of solids.[39] In a study of 138 high birth weight Icelandic infants, iron status indices at 12 months were negatively associated with cow milk consumption above 500 mL/d at 9–12 months, but were positively associated with consumption of iron-fortified breakfast cereals, fish, and meat.[40]

Meat has been highlighted as a good source of bioavailable iron and zinc, as well as protein. In a randomized trial in the United States, meat was shown to be acceptable to mothers and infants as an early CF and associated with a trend toward better behavioral outcomes at 12 month using the Bayley Scales of Infant Development,[41] whereas Danish infants randomized to receive a higher meat intake had a smaller decrease in hemoglobin in late infancy.[42] An observational cohort study in the United Kingdom also reported that meat intake from 4 to 12 months was positively and significantly associated with weight gain up to 12 months and with psychomotor development at 22 months.[43]

Protein

Protein intake in relation to energy intake is low while an infant is exclusively breast-fed (protein:energy ratio (PE) 5%) but increases markedly in infants in high-income countries during the complementary feeding period, particularly if complementary foods are consumed along with cow milk (20% PE) or infant formulas (7%–8% PE).[44] Protein intakes during this period are often two to three times higher than the theoretical requirements. In one study, figures for PE% in 9–12-month-old infants from four European countries ranged from 15.0 to 15.7, whereas infants in Italy had a very high mean intake of 19.5 PE%, a large proportion of which (13.0 PE%) came from animal foods.[45]

It has been suggested that there should be upper limits for protein intake during the first years of life, mainly based on concerns that a high protein intake may increase the risk of later obesity. However, although there is increasing evidence linking more rapid early growth to later cardiovascular risk, and randomized trials have shown adverse effects of

higher protein infant formulas on later fatness[46,47] and blood pressure,[48] these trials focused on protein intake from milk, and no randomized study has specifically addressed the issue of the protein content of complementary foods. It is also probable that different protein sources have different effects; and that dairy proteins may specifically influence IGF-1 concentrations and hence growth patterns.[49,50]

Salt and Sugar

Two randomized trials have shown that higher intakes of salt in early infancy are associated with higher blood pressure at the time,[51,52] and follow-up of one study suggested the effect persisted during adolescence.[52] Furthermore, infants may become accustomed to a salty taste which could affect their subsequent food preferences and intake. Requirements for sodium can be met by breast-feeding and subsequently from complementary foods without the need for added salt. Hence, it is generally agreed that salt should not be added to food during the complementary feeding period. Similarly, sugar is associated with the development of dental caries and with development of a preference for sweet foods. Its use should be restricted, and it is important to ensure good dental hygiene practices as early as possible.

Vegetarian Diets

If infants receive a vegetarian diet it is important that the diet includes a sufficient amount of milk (about 500 mL/d) and dairy products. It is recommended that vegan diets should be discouraged in infancy because of the risk of vitamin B_{12} deficiency that can affect neurodevelopment.[32]

TASTE AND FOOD ACCEPTANCE

An important but poorly researched area is the potential effect of the complementary feeding diet on food acceptance and subsequent food preferences. There may be “windows” in infancy during which certain tastes are more readily accepted. Infants are predisposed to like high-energy foods, to prefer sweet and salty tastes and to reject new foods. However, these predispositions may be modified by early dietary experience, and parents play an important role in establishing good dietary habits. Mennella and colleagues[53,54] have demonstrated that exposure to specific tastes *in utero* or during early infancy enhances preference for foods with those tastes into early childhood. They argue that taste

preferences are innate, but can be magnified through childhood. Preferences for healthy foods can be developed; for example, repeated early exposure to the taste of some vegetables enhances liking for those vegetables, suggesting the importance of optimizing dietary variety and including healthy foods during complementary feeding.

In the large UK ALSPAC cohort, children who were given home-cooked fruit or vegetables more often at 6 months of age were more likely to be eating a higher proportion of fruit and vegetables at 7 years than those who were given home-cooked fruit and vegetables less often. Interestingly, this effect was not seen in relation to the consumption of ready-prepared fruits or vegetables at 6 months.[55] However, this was an observational study and it is not clear whether this finding reflects differences in the flavor of home-prepared versus commercial foods, or perhaps the fact that infants given prepared fruit and vegetables came from families where subsequent opportunities to consume these foods may have been more limited.

In another analysis using data from the ALSPAC cohort, the authors developed an index reflecting the degree of adherence to complementary feeding guidelines, and explored associations between index scores and sociodemographic factors and dietary pattern scores at the age of 3 years.[56] The Complementary Feeding Utility Index consisted of 14 components, including breast-feeding duration, feeding to appetite, timing of introduction to solids, exposure to iron-rich cereals, fruit and vegetable intake, exposure to high-fat/-salt/-sugar foods including sugary drinks, food texture, and meal/snack frequency. Associations were found among index score, maternal age, education, social class, maternal smoking history, and prepregnancy BMI. After adjustment for sociodemographic factors, the index score was associated negatively associated with "processed" and positively associated with "healthy" dietary pattern scores at age 3 years, suggesting that an index of complementary feeding practices reflecting adherence to recommendations may be predictive of later dietary patterns.

METHOD OF FEEDING

In addition to the timing and content of the complementary feeding diet, it is important to consider whether the manner in which foods are given to the infant might be important. Traditionally, infants have generally been spoon-fed with first complementary foods in the form of purees, with subsequent introduction of semisolid and finger foods. However, alongside

recommendations to delay the introduction of solid foods until 6 months, there has been an increasing tendency to avoid the initial "puree" stage altogether and progress straight to finger foods. In the "Baby Led Weaning" method, which is currently very popular among parents in countries such as the United Kingdom and New Zealand, the infant feeds himself hand-held foods instead of being spoon-fed by an adult, sharing family foods and mealtimes. It has been suggested that this approach may encourage improved eating patterns and reduce the risk of overweight and obesity by providing the infant with greater control over his/her intake and encouraging more responsive parenting.[57] However, given the self-selected nature of parents and infants who currently follow this practice, it is not yet clear whether these associations are causal. Furthermore, data are lacking on whether infants who are weaned using this approach obtain sufficient nutrients, including energy and iron, or eat a more diverse range of foods. These important issues ideally need to be tested in a randomized controlled trial.

Emmett and colleagues[58] investigated the impact of the age at introduction of lumpy solid foods in a follow-up of 7821 children from the prospective U.K. ALSPAC cohort. Dietary intake and feeding difficulties were assessed at 7 years of age. Children were divided into three groups based on the age at which they were first introduced to "lumpy" solids: 12.1% before 6 months of age, 69.8% between 6 and 9 months of age, and 18.1% after 9 months. Children introduced to lumpy solids after the age of 9 months ate less of many of the food groups at 7 years, including all 10 categories of fruit and vegetables, than those introduced to lumpy foods between 6 and 9 months. In addition, they were reported as having significantly more feeding difficulties.

PARENTAL FACTORS

Parents clearly play a major role during the complementary feeding process, both in terms of decisions on the timing and content of the diet, and also the way in which the infant is fed, setting rules and expectations, and providing a role model. It is increasingly recognized that parenting style, defined as the way parents interact with a child in terms of attitudes and behaviors across different domains of parenting, including feeding can influence the infant's feeding behavior.[59] In a recent review of literature examining relationships between parenting styles and feeding behaviors and the fruit and vegetable consumption of preschool children, Blissett[60] concluded that an authoritative feeding style, which is typified by

emotional warmth and responsiveness but high expectations for children's dietary adequacy and behavior, accompanied by practices such as modeling consumption of fruit and vegetables, making these foods available within the home, moderately restricting unhealthy alternative snack foods, and encouraging children to try fruit and vegetables, is associated with better consumption in the childhood years. However, most published studies are observational and intervention studies are ideally needed to determine if changing parental feeding style and practices can favorably influence offspring food choice and feeding behavior.

CONCLUSION

The timing, content, and method used to deliver complementary feeding have potentially important effects on health outcomes, nutritional status and subsequent food choices, and feeding behaviors. Research in this field has tended to be dominated by the timing of introduction of complementary foods in the context of the optimal duration of EBF, which has the effect of excluding a large proportion of infants in many high-income countries who receive breast milk substitutes from early infancy. Greater focus on the content of the diet during this period would be beneficial in achieving adequate intakes of nutrients such as iron, while avoiding excess, and promoting the development of healthy dietary habits. The majority of studies in this field have been observational, and intervention trials are much needed to establish causal relationships which can be used as a basis for recommendations.

Energy and Substrate Regulation in Obesity

36

Daniel J. Hoffman, PhD Susan B. Roberts, PhD

Overweight and obesity are widely considered to be the major public health problems in affluent countries[1,2] and are becoming increasingly common in some economically disadvantaged societies as well.[3,4] Previously considered a problem mainly occurring in adults, overweight and obesity are now prevalent in children, with an estimated 18% of children aged 2–19 years thought to be affected.[5]

DEFINITION OF OBESITY

The definition of obesity is deceptively simple; it is a state of excessive accumulation of body fat. However, the translation of this simple definition into working standards for excess body fat and body weight has been complicated for several reasons. First, because body fatness is a continuum, the cutoff point for the definition of obesity is necessarily arbitrary.[1] In addition, the harmful effects of obesity result primarily from the excessive accumulation of fat, but there is no simple method for the direct measurement of this body compartment in individuals of any age. These concerns notwithstanding, the Centers for Disease Control and Prevention (CDC) have published body mass index (BMI; kg/m^2) percentiles for children aged up to 19 years (see Appendix), together with useable definitions for "risk of overweight" and "overweight."[6] These

definitions recognize that BMI is a better indicator of relative weight than weight for height, even if it is not precisely aligned with body fatness in all population groups.[7]

The CDC charts provide an improved set of reference growth data that have been updated and smoothed using statistical techniques. However, as reviewed elsewhere,[8] it should be noted that the latest national survey data for children ages 6 years and over were not included in the data set used to calculate the BMI percentiles because of the marked increase in weight of children ages 6 years and older in the latest survey (Third National Health and Nutrition Examination Survey [NHANES III]) compared with previous surveys. The inclusion of the latest survey data would have shifted the percentiles up and resulted in a relative underclassification of the prevalence of overweight. Because the 85th percentile of BMI is used to classify risk of overweight and the 95th percentile is used to classify overweight,[7] the data used effectively define overweight as a fixed percentage relative to population surveys before NHANES III. Thus, the BMI charts can be considered more as recommendations for the healthy range of BMI rather than as current population values because they are designed primarily to provide a reference for the diagnosis of overweight. They can also potentially be used to diagnose underweight (e.g., at the 10th or 5th percentiles), but accepted definitions for underweight are needed. One concern with using BMI to identify overweight children is the potential for misclassification.[8] The relationship between weight and height and body fat content can be weak,[9] and especially in children younger than five years when the high BMI percentiles are very close together, factors such as enhanced muscular development, large head size, and a high torso-to-leg ratio could all falsely elevate the BMI of a child with a healthy amount of body fat into an overweight range. For example, differences in head circumference between a 3-year-old child on the 10th head circumference percentile and one on the 90th percentile translate into a body weight difference of approximately 0.75 kg (assuming that the head weighs 1.7 g/cm^3 and is a sphere). A 3-year-old child's BMI would therefore vary by approximately 0.85 units depending on whether head circumference was on the 10th or 90th percentile. This could mean the difference between the 75th and 85th to 90th percentile for BMI—in other words, the difference between no weight concern and a diagnosis of risk of overweight.

The effect of the relative length of torso and legs can also be predicted using theoretical calculations. Assuming that the proportion of standing

height attributed to torso varies from 0.35 to 0.38 and that for a given contribution to height, torso weight is twice that of legs or neck,[10] BMI would vary by approximately 0.4 units. These calculations highlight the potential for misclassification of individuals, especially those between the 85th and 95th percentiles. Until improved methods for determining body fatness are routinely available, some individual judgment is needed in applying standard BMI definitions for overweight in individual children.

At the same time that the 2000 CDC percentiles were published, Cole et al[11] reported internationally derived, age-specific BMI values for children equivalent to BMI definitions of overweight (BMI = 25 or more) and obesity (BMI = 30 or more) in adults. The adult cutoff values of 25 and 30 were originally developed based on increased health risks.[12] The theoretical advantage of creating equivalent values for children is that they would provide absolute standards for fatness rather than standards relative to population fatness at any given period of survey.[13,14] It should be noted that it is not currently known whether equivalent percentiles in childhood confer similar risk to those found in adults, but because BMI tends to track from childhood through adult life, the approach seems a reasonable one.

As reviewed elsewhere,[8] Cole et al[11] obtained national survey data from six countries (Brazil, the United Kingdom, Hong Kong, the Netherlands, Singapore, and the United States). For each country, the percentiles equivalent to BMI values of 25 and 30 at age 18 years were determined, and then BMI values at different childhood ages were obtained for the same percentiles. There was substantial agreement in childhood BMI values among the six countries; thus, mean values for different ages were computed to give age-specific BMI cutoffs equivalent to adult BMIs of 25 and 30 kg/m^2. Figure 36-1 shows a comparison of the CDC 85th and 95th percentiles with the overweight and obesity cutoff points for BMI provided by Cole et al.[11] For both boys and girls, the 2000 CDC definition of overweight (95th percentile) is markedly higher than the Cole et al[11] definition of overweight, except for the period between age 4 and 5 years. In other words, by the current U.S. definition, many fewer children in the United States and worldwide are overweight. In fact, the 2000 CDC definition of risk of overweight (85th percentile) most closely approximates the Cole et al[11] definition of overweight, with the Cole et al[11] values tending to be slightly higher for ages 2–10 years and slightly lower for 17 years and older. In addition, the CDC BMI definition of overweight is not similar to the Cole et al[11] definition of either overweight or obesity, but the CDC 97th BMI percentile is similar to the Cole et al[11]

definition of obesity for the period between 7 and 14 years.

These comparisons raise the important issue that greater agreement is needed among national and international agencies with regard to definitions of what age-specific BMI values appropriately define overweight and obesity. In the meantime, the 2000 CDC percentiles for BMI might be most appropriate for assessing different degrees of overweight in U.S. children, and the BMI cutoffs of Cole et al[11] could be used for international comparisons of obesity prevalence.

RISKS OF OBESITY

The short-term risks of overweight in children and adolescents extend to reduced scholastic performance, psychological problems, and a number of significant health risks, including hyperlipidemia.[15] In addition, obese children are at increased risk of becoming overweight or obese adults compared with children of normal weight[16] and therefore are at long-term risk of the substantially increased morbidity and mortality, psychological problems, reduced economic achievement, and discrimination that are seen in obese adults.[17] In a summary of 17 studies investigating the long-term risks of childhood overweight for the development of adult obesity, Serdula et al[18] observed that 26%–41% of overweight preschool children go on to become obese adults, with the risk of adult obesity increased to 2.0–2.6 times that of nonoverweight children.

The risk of adult obesity in overweight children increases progressively with age. Data from Braddon et al[19] on changes in the risk of adult obesity according to the age of childhood manifestation are shown in Figure 36-2. In that study, which was conducted in a cohort of English children, the percentage of obese adults who were overweight at age 7 years was only 2.6% for men and 7.5% for women, whereas values increased to 13.9% for men and 25.5% for women who were overweight at age 14 years. In addition, these figures might substantially underestimate the true relationship between early fatness and later obesity because 28.6% of obese men and 36.5% of obese women were already obese or overweight by age 7, a substantially increased percentage relative to the group of children who were categorized as overweight, and again there was an increase in the number of obese adults who were overweight in childhood as age increased (Figure 36-2).

A further issue relevant to the risks of childhood overweight is that there is evidence to suggest that severe overweight developing early in life

is particularly likely to lead to adult obesity. Whitaker et al[16] showed that childhood overweight was increasingly likely to predict adult obesity from age 3 years and older. Similarly, Abraham and Nordsieck[20] reported that 72.2% of severely overweight children (weighing more than 120% of the average for the population) became obese adults; a similar result was found by others.[21] Although these data illustrate the substantial risk of childhood overweight leading to adult obesity, it is also important to note that many overweight children do not become obese adults. Data from Poskitt[22] indicate that only one in nine overweight infants remain obese as adults in England, whereas other studies similarly indicate that a minority of overweight children remain overweight.[19]

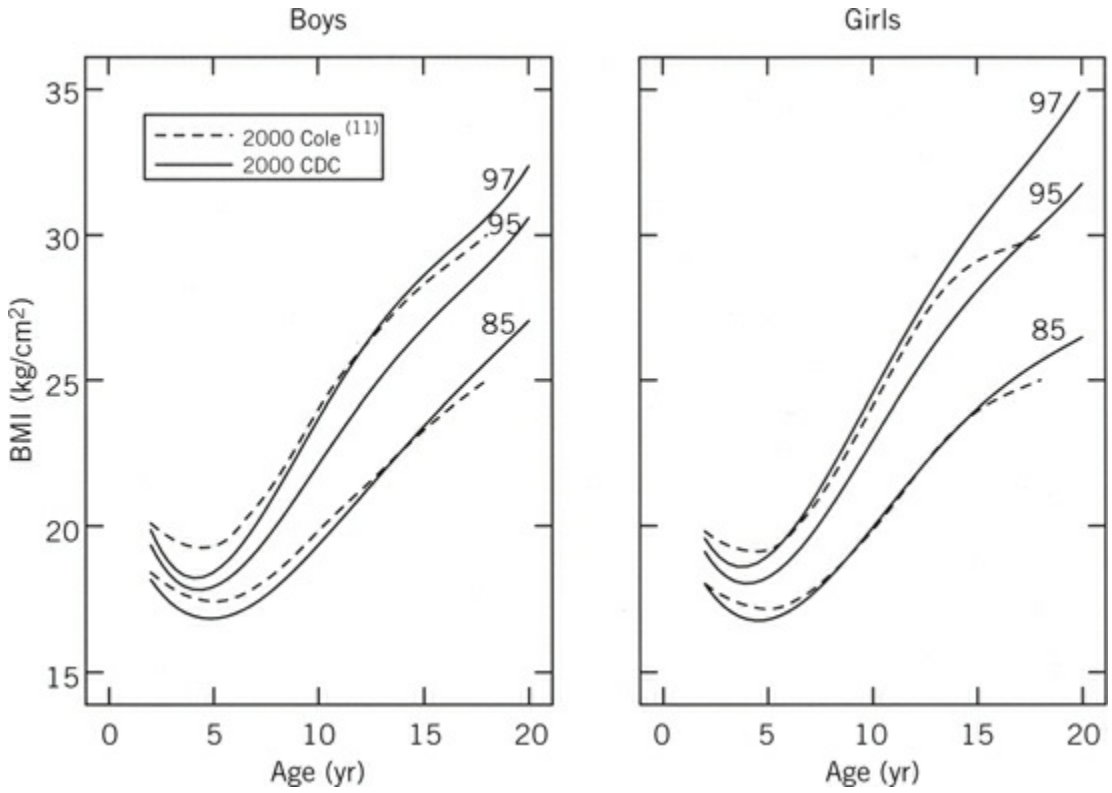

Figure 36-1 Comparison of Cole et al's[11] BMI definitions of overweight and obesity during childhood (broken line) with 2000 CDC 85th and 95th percentiles (defined as risk of overweight and overweight, respectively) and the CDC 97th percentile (*solid line*). (Adapted from Roberts and Dallal.[8])

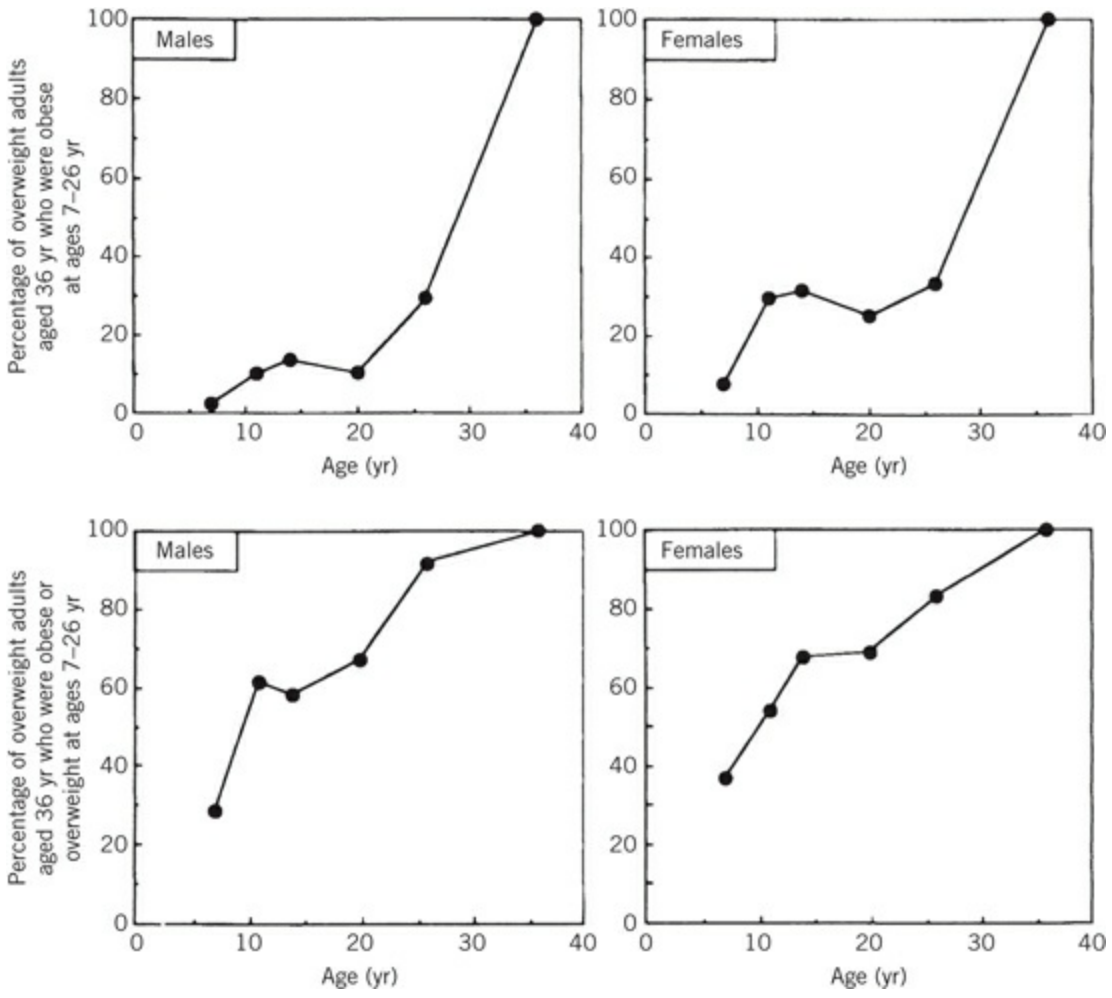

Figure 36-2 Percentage of obese men and women aged 36 years who were already obese (top) or either obese or overweight (bottom) by ages 7–26 years. (Adapted from Braddon et al.[19])

Recent studies have also raised the issue of whether, in addition to increasing the risk of adult obesity, obesity in childhood could also exert an independent influence on adult morbidity and mortality. In an analysis of longitudinal anthropometric data from the Third Harvard Growth Study (1922–1935), Must et al[23] observed that over a 55-year period, men who were overweight in adolescence had significantly increased all-cause mortality (relative risk 1.8) compared with men who were lean during adolescence. This effect of adolescent weight, confirming a similar result found previously by Mossberg,[24] persisted even when weight at age 53 years was controlled. The implication of this finding is that the effects of adolescent weight on morbidity and mortality resulted from the adolescent

obesity directly rather than from the effects of adolescent obesity on adult weight.[24] There was no association between adolescent weight and adult mortality in females in the study of Must et al,[23] and gender was not distinguished in the study by Mossberg.[24]

The mechanisms by which adolescent weight might exert an influence on adult morbidity independent of adult fatness in men and possibly in women are not known. However, reports of increased plaque deposition in the arterial walls of overweight children suggest that there could be long-term effects of early body weight on morphology or metabolism that are not easily reversible. Consistent with this suggestion is the fact that overweight girls have been shown to have a reduced age of menarche, a risk factor for developing breast cancer.[25–27] This effect appears to be primarily related to increased body size rather than to differences in dietary intake in the obese.[28–30] A study by Meyer et al[31] suggested that the lowered age of menarche in overweight girls might be associated with increased weight rather than with increased fat mass.

It is important to note that not all studies of the relationship between childhood weight and adult morbidity have reported positive associations. The study of Barker et al[32] reported an opposite trend, with a negative association between weight at 1 year of age and vascular disease in adult life.[32] Further studies are needed to clarify this issue and in particular to determine whether the long-term effects of early obesity could be important at some ages during childhood but not at other ages.

GENETIC VERSUS ENVIRONMENTAL FACTORS IN THE DEVELOPMENT OF OBESITY

Studies in Animals

There is substantial evidence that obesity in animals can be transmitted genetically.[33] Several genetically obese animal strains exist, such as the Zucker rat and the ob/ob mouse, which have substantially more adipose tissue than their lean counterparts. The fat gain in genetically obese animals is caused by a variety of mechanisms, including hyperphagia and an increased efficiency of energy use. The increased energy efficiency can be attributed primarily to a reduced thermogenesis for body temperature regulation. It is likely that some degree of imbalance in the autonomic nervous system contributes to the defective thermogenesis, as indicated by reduced sympathetic nervous drive in response to mildly cold ambient

temperatures and in response to overeating.[34] In addition, parabiotic studies, in which the circulatory systems of lean and genetically obese animals are joined, have indicated that unidentified circulating factors (or the ability to respond to them correctly) are also important in the development of obesity.[35]

Animal studies also demonstrate that obesity can result from environmental factors, most particularly the availability of high-fat or high-variety diets. Some—but not all—strains of laboratory rodents gain substantial weight and fat when offered cafeteria diets containing a variety of snack foods such as cookies, cheese, cakes, processed meats, nuts, and so forth. Similar results have also been produced by offering synthetic high-fat diets, as well as by providing sucrose solutions in addition to standard rat chow. It could be noteworthy that physical activity does not have as much of an influence on body fat content as does diet in these rodent species. The fact that only some strains of animals, and only some animals within a strain, are susceptible to this diet-induced obesity[36,37] strongly indicates that "environmentally induced" obesity occurs only in genetically susceptible individuals and should therefore really be viewed as a genotype–environment effect. In relation to this observation, it is important to note that the willingness to overconsume food is not entirely a result of absolute standards of taste in animals. Instead, in studies that have separated the process of eating from the process of digestion by the use of esophageal cannulae, it has been shown that unidentified postingestion factors play a dominant role in determining food preferences.[36]

Studies in Humans

Studies on the importance of genetic inheritance versus environmental factors in the development of overweight and obesity have been harder to conduct in humans. It is widely accepted that body fat mass and fat distribution are subject to significant familial transmission[38–43]; in other words, the body compositions of children to a large extent reflect those of their parents. There remains a great deal of uncertainty, however, over the relative importance of genetic inheritance and environmental transmission (transmission between generations through the sharing of common environmental circumstances) in determining body fat content. Reported values for genetic heritability range from negligible to 0.8, implying that genetic inheritance accounts for between 0% and 80% of the variability in body fat mass in the community, and rates of environmental transmission range almost as much.[39,41,43–55]

This uncertainty over the relative importance of genetic and environmental transmission probably relates in large part to the methods that have been used to measure body composition and to the populations that have been studied. Most previous studies have used simple anthropometric indicators of body fat mass, such as weight corrected for height or one or more skinfold thicknesses.[39,43–48,50–55] However, the relationship between anthropometric parameters and fat mass can be very weak.[9] In addition, muscle mass, bone size, and height appear to be strongly inherited.[43] This could help explain the genetic inheritance of indicators of apparent fatness based on weight and could indicate that weight measurements will tend to result in an overestimation of the genetic inheritance of fat mass.

Bouchard et al.[49,56] used hydrostatic weighing (a gold standard method) for assessment of body composition. Data from these investigations indicate that there are significant genetic and environmental components to the transmission of body density, with genetic inheritance accounting for 25% and environmental transmission for 30%. Elder et al[57] recently used several different methods and reported that the heritability of body fatness was 60%, and unique environmental factors accounted for 20%. Similar results were obtained by Dubois et al.[58] Thus, it appears that the family environment is less important than genetic inheritance in determining body fat mass.

Other lines of evidence from studies that effectively separate genetic inheritance from environmental factors confirm the existence of significant environmental factors in human overweight and obesity. For example, the body fat content of unrelated married couples becomes more similar over time.[40] In addition, the prevalence of obesity varies by the season of the year (it is highest in the fall and winter) and location within a country.[59] As further evidence, surveys show that the prevalence of childhood obesity has increased in the United States during the past two decades despite a relatively stable population pool.

METABOLIC PROGRAMMING IN THE DEVELOPMENT OF OBESITY

There is increasing awareness of the possibility that there might be critical periods during the life span when diet and other environmental factors exert a long-term influence on body fat content and the risk of adult obesity in humans,[60–64] a potential event that has been termed “metabolic

programming." As emphasized by Lucas,[60,61] the fact that this tremendously important issue has not yet been resolved reflects the relative lack of randomized dietary intervention trials with long-term follow-up in infants and children. More studies of this type are needed despite the complex ethical issues involved. Nonetheless, a body of evidence has developed to the point that several potential mechanisms to explain "metabolic programming" now exist.[64] Perhaps more important is the fact that several studies now suggest that maternal influences on such programming may not only have epigenetic mechanisms, but such epigenetic changes may persist beyond one generation.[65]

Evidence consistent with the view that metabolic programming of adult body fatness might exist at different ages comes from several sources, in particular indicative of the possibility that either long-term energy insufficiency or long-term energy excess in childhood can lead to excess body fat content in adult life. In 1976, Ravelli et al[66] published the first study suggesting that nutrition of the mother during the intrauterine period might have a long-term influence on the risk of obesity. Specifically, the investigators followed the incidence of obesity among men whose mothers lived in Holland during the Dutch "Hunger Winter," a time when the food supply was reduced in specific areas of the country at the end of the World War II. A significant *increase* in the incidence of obesity at age 19 years was noted among the male offspring of mothers whose energy intake was reduced to famine levels (estimated at approximately 600 kcal/d) specifically during the first trimester of pregnancy, whereas a significant *decrease* in the risk of obesity was observed in women who had undergone energy deprivation during the third trimester. Although "metabolic programming" of intrauterine malnutrition can explain this result, it is also possible that other factors were important. For example, the mothers who were deprived of food might have been particularly concerned about feeding their infants substantial amounts of food after giving birth. In addition, the food provided by the Allied Forces after the famine was extremely high in fat, and the possibility cannot yet be ruled out that this might have had an important long-term effect. More recent studies in humans are consistent with the Ravelli data, suggesting, for example, that low birth weight is associated with significantly greater abdominal adiposity later in life.[67]

Recent studies in animal models have also reported that malnutrition during the early part of pregnancy can be associated with increased body fat in adult life,[68,69] with leptin resistance suggested as one possible

mechanism[70] supporting the belief that long-term metabolic changes can be induced through diet. Although the mechanism for this effect is not known, Anguita et al[69] suggest that morphologic changes in the hypothalamus might be important.

Similar to in utero energy insufficiency, childhood stunting (which is widely considered an indicator of chronic energy insufficiency during early childhood and typically occurs before age 5) has also been correlated with high BMI in several transitional countries, such as Brazil, China, and South Africa.[4,71–74] The risk for obesity and overweight for adults who were stunted as children and adolescents varies among countries but is consistently positive.

The relative risk for obesity for an adult who was stunted in childhood is 1.7 in Brazil, 2.6 in South Africa, and 7.8 in Russia.[71] At the same time, one study from South Africa reported no association between stunting at age 2 years and indicators of excess fat mass (BMI and waist circumference) at age 8 years.[75] Thus, controversies regarding these associations remain, mostly due to the fact that mechanisms to explain these associations remain unclear; however, recent studies have offered possible metabolic as well as behavioral evidence that might explain part of this association.

In perhaps the first piece of evidence that early nutrition has long-term effects on metabolism that predispose a child to subsequent obesity, Hoffman et al[76] reported that nutritionally stunted children have a higher respiratory quotient and lower fat oxidation compared with healthy children from the same environment (Figure 36-3). When these children were studied four years later, it was found that the stunted children had gained more body fat as a proportion of body weight compared to the control children (Martins, PA 2005). This would suggest that not only are they metabolically predisposed to obesity, but the effects appear well before adulthood. In the same series of experiments, stunted children also appeared to have impaired regulation of food intake compared with control children from the same environment,[77] resulting in greater energy consumption per kilogram of body weight when the stunted children were exposed to an abundant, ad libitum diet (Table 36-1). The results of this study need to be replicated but are consistent with the hypothesis that exposure to food insecurity early in life can disrupt normal perceptions of hunger and satiety. Additional support for suggesting that metabolic adaptations occur following chronic undernutrition comes from a study of Buryat tribes in Siberia where it was reported that adults who were stunted

compared to their peers had a lower rate of fat oxidation,[78] consistent with the study from Brazil. Taken together, these studies provide multiple lines of evidence consistent with the suggestion that undernutrition during early life can have long-term metabolic effects that can promote obesity later in life.

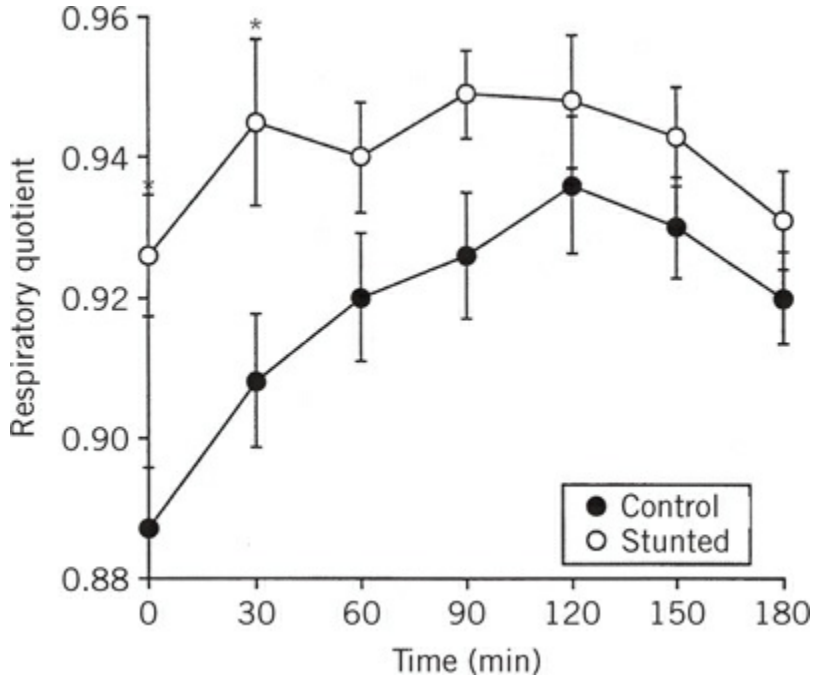

Figure 36-3 Fasting and postprandial respiratory quotient (RQ) in stunted and control children.[60] Values are means ±SEM. The stunted children has a significantly higher fasting RQ compared with control children (t = 0) and postprandially at t = 30 min ($P < 0.05$). The average postprandial RQ was not significantly different between the two groups ($P = 0.10$). (Reproduced with permission from Hoffman et al.[69])

The first months after birth have received considerable attention as another potential time when metabolic programming, through the choice of diet (breast milk or formula) and the time of weaning, could have a long-term influence on body fatness. In particular, although several studies have suggested no effect of formula feeding on body fatness, the more recent studies have consistently indicated that breast-fed infants tend to become leaner adults.[79–87] Additionally, the duration of breast-feeding may have a u-shaped relationship with adult body fatness, indicated by recent finding that although 5–7 months breast-feeding is associated with lower rates of adult overweight than 0–2 months of overfeeding, breast-feeding of greater than 8 months was also associated with elevated rates of overweight at 60 years of age.[88] The finding of a tendency for formula feeding to promote later body fatness in full-term babies is consistent with preliminary findings from randomized studies in preterm infants[89] and also with the well-known effect of early overfeeding in rodent models (resulting in a permanent increase in body weight and fat content).[90] Additionally, similar results have been demonstrated in nonhuman primates.[91]

Further studies are needed to determine whether metabolic or behavioral influences of formula versus breast-feeding are responsible for the differences observed. However, of potential relevance to this issue is the fact that Singhal et al[89] conducted a prospective study of preterm infants who were fed either a standard infant formula, banked breast milk, or an enriched preterm formula (5 g protein/L and 9 g fat/L greater than the standard formula) to examine long-term effects on circulating leptin.

Between the ages of 13 and 16 years, the children were measured for body fatness and leptin concentrations. It was found that the children who had received the preterm formula had a 30% higher ratio of leptin to fat mass compared with both of the other groups,[89] suggesting that the excess energy intake or altered nutrient composition of the preterm formula might have programmed higher circulating leptin during adolescence.

ENERGY AND SUBSTRATE REGULATION IN OBESITY

Energy Regulation

Average nonoverweight children consume more than two million kilojoules a year, but their body fat stores increase only modestly if growth is normal and energy expenditure approximates energy intake. A change of only 10%, either in intake or output, can lead to a 15-lb change in body fat in a single year, in addition to that deposited as a normal consequence of growth. The majority of children, who are of normal weight, do not exhibit such undesirable changes in body weight and fat, implying that normal energy regulation must be remarkably sensitive.

Until recently, our understanding of the underlying cause of this sensitive energy regulation was dominated by the guiding principle of energy balance:

$$\text{Energy stored} = \text{Energy intake} - \text{Energy expenditure}$$

Thus, it has been recognized that high levels of body fat (i.e., energy) cannot have been accumulated without energy intake being unusually high or energy expenditure being unusually low, or a combination of these two options. Similar calculations to those given above can illustrate that the dysregulation of energy in obesity needs to be only very small for excess adipose tissue to accumulate. For example, a child who becomes 100 lb overweight by the age of 15 years needs to have eaten less than an extra approximately 100 MJ/d between the ages of 5 and 15 years. There has been considerable interest in defining whether energy intake or energy expenditure is the primary factor determining this energy dysregulation in obese individuals, as well as seeking to identify metabolic mechanisms that determine the separate regulation of these parameters. As described below, most of the investigations conducted in children have been cross-sectional in nature, that is, comparing measurements of energy intake and expenditure between lean and obese individuals or examining the relationship between these parameters in groups of individuals differing widely in body composition. It is also important to recognize that there may have been changes in the relative importance of excess energy intake and low-energy expenditure over time, reflecting shifting food behavior patterns and physical activity norms.

Energy Intake

The energy intake of an individual is usually understood to be that energy available to the body after obligatory losses of energy in urine and stools. Although complex metabolic balance studies are needed to precisely determine this “metabolizable energy,” it can also be predicted from the

dietary intakes of protein, fat, carbohydrate, and alcohol using the standard conversion factors of 4.0, 9.0, 4.0, and 7.0 kcal/g, respectively, which take into account the obligatory losses.

The regulation of food intake clearly plays an important part in the sensitive energy regulation in children of normal weight. More than 70 years ago, Davis[92] demonstrated that very young children of normal body weight are capable of choosing a balanced diet and maintaining normal growth without dietary intervention from adult caregivers. This remained true over periods of several days or longer, although food choices at individual meals were frequently extremely erratic. More recently, Birch et al[93] and Shea et al[94] provided additional strong evidence in support of an important role for the regulation of food intake in the energy regulation of young children of normal body weight. These investigators showed that although there might be substantial meal-to-meal fluctuations in energy and nutrient intakes, prompt and appropriate compensation occurs spontaneously so that the 24-hour energy intake remains relatively stable. A further report by Birch et al[95] also demonstrated that young children are able to compensate for the inclusion of low-calorie fat substitutes in a meal to maintain a constant energy intake.

These studies clearly demonstrate that in children of normal body weight, energy regulation through the regulation of food intake occurs and plays an important role in the maintenance of a stable pattern of body composition change throughout childhood. However, a caveat to these studies is that the observed capacity for normal energy regulation may occur only when relatively healthy foods are offered, and the ability of young children to accurately regulate energy intake when offered many highly energy dense foods of low nutritional value has not been systematically explored.

Individual studies of differences in reported energy intake between overweight and nonoverweight children have been conflicting, but taking all of the data together, reported energy intakes of overweight children are not significantly greater than those of nonoverweight children of the same age and are significantly less when expressed in relation to body weight.[29,94–113] However, it is known that overweight individuals, including adolescents,[114] underreport their energy intake to a greater degree than do individuals of normal weight, which indicates that the finding of normal food intake in overweight children might be owing to methodological error.

In contrast to the studies of reported energy intake, studies from psychological investigations of eating behavior in overweight children

suggest that already overweight children consume more total energy than do nonoverweight subjects. Studies by several groups have suggested that overweight children and adolescents are faster eaters, chew less, prefer high-fat foods, and do not exhibit the normal pattern of decelerating eating toward the end of a meal, as seen in children of normal weight.[115–119] They may also consume more sugar sweetened beverages. Furthermore, obese parents have been reported to give more encouragement to their children to eat than do parents of nonobese children and serve them larger portions of food.[120] These findings are also consistent with results from studies in adults.[121] In addition, overweight children may have an abnormal pattern of energy consumption within the day, with a reduced percentage of calories being consumed at breakfast, which is a meal widely recognized to be associated with prevention of weight gain in adults.[122] As described below, studies of total energy expenditure (TEE) might be more reliable for estimating the energy intake of overweight children than studies of reported energy intake and confirm that already overweight children consume more total energy than children of normal weight. A recent summary of TEE data in children concluded that high energy intake rather than low TEE could explain secular increases in body weight during the period 1985–1995, a suggestion that is consistent with increases in per capita food supply during this time.[123]

Energy Expenditure

The TEE of an individual, which is equal to the metabolizable energy intake when body energy stores remain constant, can be divided into compartments that relate to the different types of energy expenditure measurements that are made. Typically, three major compartments are defined. The resting energy expenditure is the energy expended at rest after an overnight fast and is the major compartment, comprising at least half of the TEE in a typical individual. The thermic effect of feeding is the increase in energy expenditure above baseline resulting from the consumption and processing of food and comprises 7%–15% of TEE on average. This thermic effect of feeding has been further subdivided into facultative and obligatory components, where obligatory energy expenditure is the expenditure for necessary aspects of digestion and assimilation, whereas the facultative component has been proposed as a form of energy wasting that can perhaps serve to burn off surplus dietary energy. The final component of TEE is the energy expended for physical activity and arousal, which is generally the second largest component of

TEE and the most variable because to a large extent it is under voluntary control.

The role of energy expenditure in the regulation of energy balance has been controversial in the past but is perhaps less so currently. Studies in both adults[124–128] and adolescents[129] have suggested that humans have a relatively limited capacity for dissipating surplus dietary energy by thermogenesis. In these studies, subjects have been overfed, and changes in energy expenditure and energy storage have been measured to assess the fate of the excess dietary energy. In all carefully controlled studies, the ability to dissipate excess energy, seen as an increase in TEE or components of energy expenditure, has represented a relatively minor component of the excess dietary intake.[124–128]

Thus, the majority of the surplus energy was stored, primarily in the form of additional body fat. Studies of this kind highlight the importance of the regulation of food intake, rather than thermogenesis, in the short-term regulation of energy balance.

It is possible, however, that energy expenditure plays other critical roles in energy regulation that these studies do not address. In particular, it has been speculated that low-energy expenditure in one or more of the components of expenditure could have an association with increased body fatness over the long-term. This could be a result of the low-energy expenditure promoting increased fatness or of an underlying mechanism promoting fat gain that precipitates low-energy expenditure to provide the surplus energy needed for the weight gain. Studies of differences in components of energy expenditure between obese and nonobese children are discussed below. These cross-sectional studies do not define the causal role of energy expenditure in obesity but do serve to define the energy expenditure of children who are already obese in relation to normal values. Prospective studies that have investigated the role of energy expenditure in the weight gain in obesity are discussed in the section “Roles of Energy Intake and Expenditure in the Development of Obesity.”

Concerning resting energy expenditure, a summary of studies in otherwise healthy overweight and nonoverweight children reveals that the overweight individuals do not have reduced resting energy expenditure. In relation to age, the resting energy expenditure of overweight children appears to be within the normal range at 8–10 years and increases subsequently compared with values of normal children (Figure 36-4). Values for energy expenditure per unit of fat-free mass (the metabolically active component of the body because fat mass is relatively metabolically inactive) are somewhat lower in overweight compared with nonoverweight

children. However, this is an inappropriate method of expressing resting energy expenditure in individuals of different sizes because there is a wide variability in the energy expenditure of different tissues that comprise the lean mass. Tissues such as brain and heart have a very high-energy expenditure and tissues such as muscle have a low-energy expenditure. It appears that overweight and nonoverweight individuals have more similar amounts of tissues with high-energy expenditure than they have tissues with low-energy expenditure. Thus, it is more appropriate to examine the relationship between fat-free mass and resting energy expenditure than to compare resting energy expenditure per unit of fat-free mass between different groups.

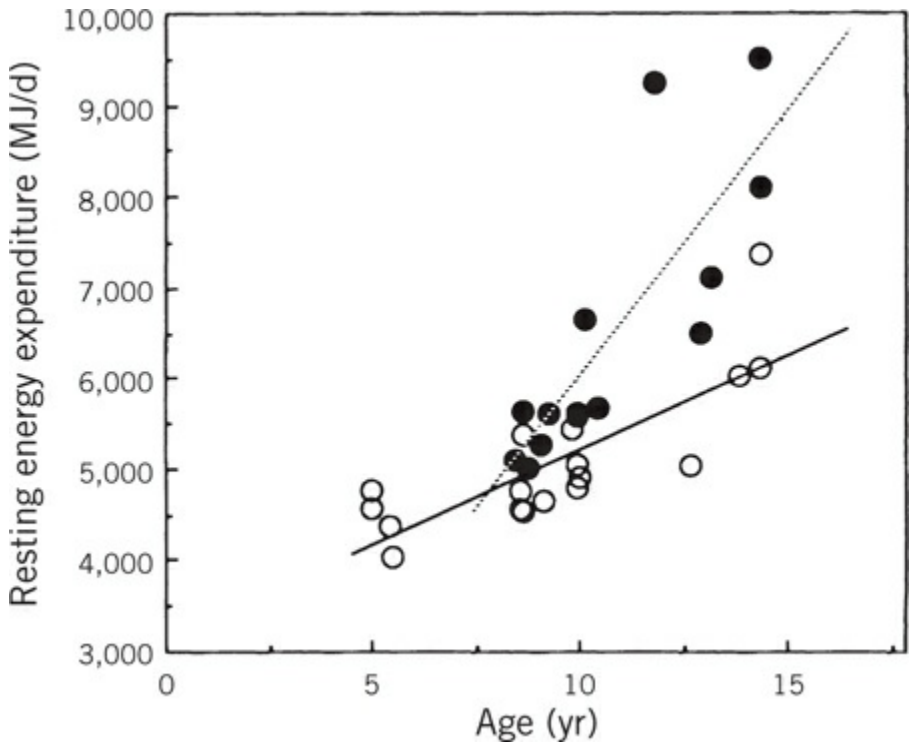

Figure 36-4 Relationship between resting energy expenditure (in kJ/d, where 1 kJ = 0.239 kcal) and age in nonoverweight (*solid line*) and overweight (*broken line*) boys and girls aged 5–15 years.[171] Data points are group means reported between 1989 and 1994.[92,103,122,132,137,141,144,172–178] There was a significant effect of obesity status on the relationship between resting energy expenditure and age ($P < 0.001$), and the relationship between resting energy expenditure and age was significant in both nonoverweight ($r^2 = 0.630$, $P < 0.000$) and overweight children ($r^2 = 0.682$, $P < 0.000$).

As seen in Figure 36-5, neither the intercept nor the slope of the relationship differs between obese and nonobese individuals, demonstrating that there is no difference in the resting energy expenditure of overweight and nonoverweight children when the data are appropriately normalized for metabolically active tissue. This result, obtained by combining data from studies in which data from at least two groups of subjects were available, is compatible with results from regression analyses in a group of children with a wide range of body compositions,[130] as well as with results of numerous studies in adults.[131]

Several studies on the thermic effect of feeding demonstrate a normal energy expenditure in overweight compared with nonoverweight children and adolescents,[129,132,133] a result that contrasts with the numerous studies that indicate a reduced thermic effect of feeding in obese adults.[134,135] There is one report of a reduced thermic effect of feeding in obese children,[136] and the duration of obesity has been implicated as a possible explanation for differences in results among different studies.[132] This explanation could also help explain the fact that the thermic effect of feeding is reduced in obese adults.

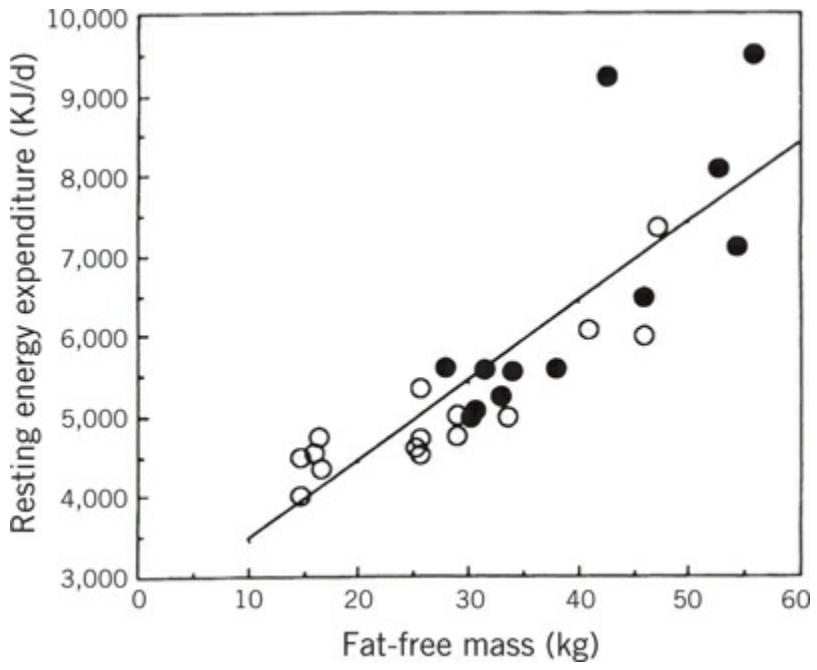

Figure 36-5 Relationship between resting energy expenditure and fat-free mass in nonoverweight and overweight boys and girls aged 5–15 years.[171] Data points are group means (in kJ/d, where 1 kJ = 0.239 kcal)

reported between 1989 and 1993.[103,122,132,141,144,172–178] There was no significant effect of overweight status on resting energy expenditure in multiple regression analyses, including fat-free mass as an independent variable. The relationship between resting energy expenditure and fat-free mass is significant (r^2 = 0.712, P < 0.000).

Concerning physical activity, several studies have reported no difference in physical activity between lean and overweight children,[71,87,137,138] whereas other studies have reported low[114,123,139–142]or even high[143] levels of physical activity in overweight children relative to nonoverweight controls.

Television viewing has also been investigated separately as a marker for low physical activity and for its relationship to body composition in children.[144] Although the mechanism by which television viewing might influence body fat mass is not known, a reduction in physical activity is strongly implicated as part of the mechanism because television viewing is a sedentary activity that might replace more strenuous ones, together with the possibility that dietary intake could be increased as well.[145,146] Studies in this area have not produced consistent results, with some studies reporting a negative association between the time spent watching television and body fatness[145,147] and other studies failing to substantiate this result.[138,148]

This controversy might reflect the fact that inactivity during television viewing can potentially be compensated for by strenuous activity at other times; more research is needed to elucidate the relationship between body fat mass and physical activity in children as well as in adults. A further unresolved aspect of the literature on television viewing is that there are reports of both a decrease[137] and a normal[149] resting energy expenditure during television viewing in obese children compared with nonobese controls.

On the basis of the studies described above, it cannot be concluded that the obese child is necessarily inactive, or that inactivity is an important cause of obesity. However, this conclusion does not exclude an important role for physical activity in obese children, and further studies are needed to clarify this important issue.

Studies on TEE as determined using the doubly labeled water technique[150,151] have been conducted as a way to examine the combined effects of different components of energy expenditure in normal-weight and overweight children and also as a more accurate way to assess energy

expenditure for physical activity (when combined with measurements of resting energy expenditure). Using this method, several studies in children and adults have indicated an inverse association between energy expenditure for physical activity and body fat mass when values for physical activity are normalized for body size by the use of the ratio of total to resting energy expenditure as a physical activity index.[106,152,153] and one recent study reported no difference between lean and overweight children despite differences in sedentary behavior and sports participation.[154] The mechanism of this association is not known but is likely to include the fact that inactivity promotes insulin resistance and could enhance fat oxidation.[155] Although this ratio of total to resting energy expenditure is reduced with increasing body fat content, the TEE for physical activity is typically high. This is because resting energy expenditure and the energy costs of most activities increase with body size. These consistent findings contrast with the substantial controversy over the effects of obesity on physical activity when studies using reported estimates of physical activity are considered.

Doubly labeled water measurements of TEE have also been used to examine differences in energy intake and energy requirements between normal-weight and overweight children. The recent Dietary Reference Intakes for Macronutrients[156] summarized all available data on TEE in childhood to report that there is no substantial difference between normal-weight and overweight children in the relationship between TEE and body weight, height, and age, with equations suitable for all children based on summaries of all available doubly labeled water data:

$$\text{TEE (kcal/d)} = 89 \times \text{weight (kg)} - 100 \text{ (boys and girls 0–2 years)}$$

$$\text{TEE} = 88.5 - 61.9 \times \text{age (years)} + \text{PA} \times 26.7 \times \text{weight (kg)} + 903 \times \text{height (mm)} \text{ (boys 3–18 years)}$$

$$\text{TEE} = 135.3 - 30.8 \times \text{age (years)} + \text{PA} \times 10.0 \times \text{weight (kg)} + 934 \times \text{height (mm)} \text{ (girls 3–18 years)}$$

where PA is a physical activity coefficient used for children 3 years and older:

PA = 1.00 if physical activity level is sedentary.

PA = 1.13 if physical activity level is low.

PA = 1.27 if physical activity level is active.

PA = 1.45 if physical activity level is very active.

TEE does not equal energy intake in children because there is additional consumed energy used for growth that is deposited in the form of lean tissue and fat. However, except during the early months of life and during the peak of pubertal development, energy used for energy deposition is only 20–25 kcal/d[156]; thus, TEE closely reflects energy intake. The equations given above indicate that children who are overweight do indeed need more energy to maintain current body weight than do normal-weight children. For example, a child more than 3 years of age who is already overweight by 10 kg compared with normal-weight children will have increased TEE and hence energy intake of 100–267 kcal/d. Table 36-2 summarizes estimated energy requirements for children of reference weights, based on the above equations with an increment added for the energy deposition in normal growth.

A final issue to consider when comparing differences in energy expenditure between lean and overweight individuals is the energy expenditure response to overfeeding. As detailed above, an ability to burn off surplus dietary energy has been suggested as potentially important in the regulation of energy balance. However, in a study of overweight and nonoverweight adolescents, Bandini et al[157] found no difference between groups in the ability to dissipate excess energy intake. This finding is consistent with the view, outlined above, that diet-induced thermogenesis plays only a small role in the regulation of energy balance.

Substrate Balance

As an extension of the energy balance principles detailed above, it has been suggested that body carbohydrate balance could play a critical role in overall energy regulation.[157] The basic principle behind this theory of energy regulation, which is in keeping with the earlier glucostatic theory of energy regulation, is that balance of the primary energy substrates, fat and carbohydrate, have to be considered separately.[158] Thus:

TABLE 36-2 Estimated Energy Requirements[a]

Age	Reference Weight (kg)	Activity Level (kcal/d)			
		Sedentary	Low Active	Active	Very Active
Boys					
1 mo	4.4	472	(No activity level specified before 3 y)		
6 mo	7.9	645			
12 mo	10.3	844			
18 mo	11.7	961			
24 mo	12.7	1,050			
3 y	14.3	1,162	1,324	1,485	1,683
6 y	20.7	1,328	1,535	1,742	1,997
9 y	28.6	1,530	1,787	2,043	2,359
12 y	40.5	1,798	2,113	2,428	2,817
15 y	56.3	2,223	2,618	3,013	3,499
18 y	67.2	2,383	2,823	3,263	3,804
Girls					
1 mo	4.2	438	(No activity level specified before 3 y)		
6 mo	7.2	593			
12 mo	9.5	768			
18 mo	11.0	899			
24 mo	12.1	997			
3 y	13.9	1,080	1,243	1,395	1,649
6 y	20.2	1,247	1,451	1,642	1,961
9 y	29.0	1,415	1,660	1,890	2,273
12 y	41.6	1,617	1,909	2,183	2,640
15 y	52.0	1,731	2,057	2,363	2,870
18 y	56.2	1,690	2,024	2,336	2,858

[a] Values are estimated average requirements from Dietary Reference Intakes.[143]

$$\text{Fat stored} = \text{Fat intake} - \text{Fat oxidation}$$
$$\text{Carbohydrate stored} = \text{Carbohydrate intake} - \text{Carbohydrate oxidation}$$

Because the energy in carbohydrate stores is very small in relation to that in fat stores, the carbohydrate stores have a high turnover rate and are liable to be depleted quickly and frequently. The essential requirement of key tissues for glucose suggests that signals should exist to efficiently monitor and correct body carbohydrate balance. An extension of this theory of nutrient regulation is that dietary macronutrient composition plays an important role in determining body fat content.[158] This is because the higher the dietary fat content, the more total food (and energy) needs to be consumed to maintain carbohydrate intake and therefore carbohydrate stores, and the fatter the individual will be because of increased energy intake.

Flatt[158] has also suggested that the increase in body fat induced by a high-fat diet could be self-limiting because reduced insulin sensitivity and increased circulating free fatty acids tend to occur with increased body fat

content, promoting increased fat oxidation and preservation of carbohydrate stores, resulting in a stabilization of hunger and satiety signals from body carbohydrate stores and stability of food intake and body fat stores. This model provides a potential explanation for body fat regulation that does not rely on the concept of a novel "signal" from fat stores that detects and corrects a body set point.

Support for the importance of nutrient balance in the overall regulation of energy balance can be derived from several sources, although there is currently little information available on infants and children. Flatt[158] has demonstrated in mice the critically important idea that energy balance is indeed adjusted on a day-to-day basis to maintain stable body carbohydrate balance, through adaptive fluctuations in food intake. Studies in humans have indicated that carbohydrate balance is more closely regulated than fat balance.[159,160] Concerning the effect of dietary composition on energy intake and body composition, animal studies have repeatedly demonstrated that hyperphagia and obesity can be induced in many strains of normal-weight rodents by feeding a high-fat diet as described above.[36]

In humans, results from some,[161–164] although not all,[164–167] short-term intervention studies in adults indicate that energy intake increases with consumption of a high-fat diet. The fact that not all human studies have found an increase in energy intake with consumption of a high-fat diet does not invalidate the nutrient balance theory of energy regulation because a high-fat diet could induce positive energy balance by decreasing energy expenditure, rather than increasing energy intake as suggested by both animal and adult human studies.[168,169] Also consistent with the nutrient balance model are the data from cross-sectional studies that indicate that consumption of a high-fat diet is frequently associated with high body fat mass in adults.[170–174] Thus, as predicted by the nutrient balance model above, obese and overweight adults tend to consume a high-fat diet than do nonobese subjects and, at least in the short-term, might be hyperphagic.

Some,[142,143] but not all,[87] studies in children and adolescents support the view that high dietary fat intake is associated with obesity. It is possible that this controversy could be owing to the fact that the fiber content of the diet and its energy density might have significant effects on food intake. Although high-fat diets tend to be low in fiber and have a high energy density, this is not always so, and differences in these aspects of the diet (unreported in the studies described above) might have been important. However, an impairment in total fat oxidation is unlikely to

explain an association between dietary fat intake and the development of obesity in review of the several recent reports in children[175–177] that rates of total fat oxidation are equivalently responsive to change in dietary intake in both lean and overweight children. There is also some suggestion that endogenous fuels are less readily oxidized in overweight to lean individuals[178] which requires further study. An additional important consideration in relation to dietary intake is that on theoretical grounds, saturated fat can be expected to have more adverse effects on body fat mass than other fats do because of its influence on insulin sensitivity.[155] and indeed several recent studies have reported lower oxidation of saturated fats than mono-or polyunsaturated fats.[179,180]

ROLES OF ENERGY INTAKE AND EXPENDITURE IN THE DEVELOPMENT OF OBESITY

As described above, the majority of published investigations into the causes of early overweight have been cross-sectional in nature, that is, they have related measurements of body fat mass to energy expenditure or other parameters measured at the same time. This approach provides important information on energy intake, energy expenditure, and substrate oxidation in individuals who are already obese but does not address the question of what happens during the development of the obese state. A finding, for example, of high energy intake in overweight children does not preclude the possibility that energy intake was normal or even low during the period of excess weight gain. Recent prospective studies have addressed the issue of causality in overweight by investigating whether energy expenditure is low in individuals with increased susceptibility to overweight (because of parental obesity). Although, the results have been conflicting, with reports of both low-energy expenditure[181–185] and normal energy expenditure[186–188] in the pre-overweight state the current weight of evidence indicates that low-energy expenditure is a contributing factor in some circumstances.[189]

SUMMARY AND IMPLICATIONS FOR THE TREATMENT OF OBESITY

The excess fat mass that characterizes obesity is attributable to both

genetic susceptibility and environmental factors and results from energy intake exceeding energy expenditure plus the energy requirement for normal growth over a prolonged period of time. However, this increment in energy intake over energy expenditure can be as little as 400 MJ/d or less if it persists over a period of years. The studies summarized in this chapter do not provide definitive evidence as to whether this differential between energy intake and energy expenditure is caused primarily by decreased energy expenditure or by increased energy intake. However, the weight of evidence currently indicates that both overeating and under-expending can be primary causes of overweight in childhood, and that once a child is overweight, energy intake is higher than that of normal-weight children. In addition, dietary fat, in particular saturated fat, can promote fat deposition through its influence on energy intake.

Further studies are needed in this area, in particular to delineate the usual roles of high energy intake and low-energy expenditure as causal factors in excessive weight gain leading to overweight in childhood. Current prescriptions for the treatment of childhood overweight, taking into account the degree of caution that is appropriate for a disorder in which the treatment can itself have detrimental consequences, should be based on individualizing for each child a decrease in energy intake relative to energy expenditure by a combination of moderate dietary therapy and promotion of energy expenditure from physical activity (see Chapter 37, "Evaluation and Management of Obesity").

Evaluation and Management of Childhood Obesity

37

Alison G. Hoppin, MD and Janey S. Pratt, MD

INTRODUCTION

At the beginning of the twenty-first century, poverty and under-nutrition have worsened in some countries, while over-nutrition and obesity have reached epidemic levels in many others.[1] Currently, obesity is the most important nutritional problem globally, and the associated medical problems account for substantial morbidity, mortality, and healthcare costs in developed countries. In developing countries undergoing rapid changes in economic and technological development, the population is exposed to rapid changes in diet and energy balance; this "nutrition transition" presents unique health challenges.[2] Understanding the mechanisms causing obesity and associated medical problems will be essential to reverse the global trend toward obesity and its threats to public health.

EPIDEMIOLOGY

Relevance and Significance

In 2012, about 15% of children and adolescents in the United States were overweight, and 18% were obese.[3] Hispanic, Black, and American-Indian children are disproportionately affected. The prevalence of obesity in US children and adolescents tripled between the 1960s and 2000, but subsequently plateaued. Meanwhile, obesity rates continue to rise in some subpopulations (e.g., Black and American-Indian girls in California), while

declining in others (e.g., children in New York City). Similar but more gradual increases in obesity were seen in most resource-rich countries worldwide during the last part of the twentieth century,[1] and in a few of these populations obesity rates are beginning to plateau or decrease slightly.[4] The highest rates of childhood obesity are in North and South America and much of Europe, with somewhat lower rates in Nordic countries, Russia and Eastern Europe.

Determining the specific causes of this rapid increase in rates of obesity is essential, yet remarkably complex. Both genetic and environmental factors have been shown to contribute significantly to this problem. In general, genetic factors explain a large part of the variation of body weight within a given population in a common environment, while environmental factors tend to explain changes in obesity over time in that population. The study of Pima Indians provides an important example of the interaction between environmental and genetic factors.[5] The Pima Indians who live in the southwestern United States are strongly predisposed to obesity and diabetes, and these traits assort in patterns indicating genetic inheritance. The genetically similar Pima living as subsistence farmers in Mexico have substantially lower rates of obesity and diabetes. Genetic factors clearly explain a large part of the obesity among Pima Indians in this country, while environmental factors likely explain the dramatic difference in rates of obesity between the two Pima populations.

Epidemiologists have used cohort studies and case-control designs to determine which environmental factors may contribute to obesity. Such studies have pointed to dietary trends, sedentary lifestyle, decreases in structured physical activity, psychosocial stressors, and cultural trends as likely contributors to the obesity epidemic.[1,2] A number of dietary factors have been proposed to play important roles. These include marked increases in the proportion of foods consumed from restaurants and fast food outlets, increasing portion size served at restaurants, increased consumption of sugar-sweetened beverages, consumption of energy-dense foods (i.e., lower water content, usually correlated with higher fat and carbohydrate content), and lower intake of fruits and vegetables.[6,7] Other factors include decreases in structured physical activity, particularly for children, increasing sedentary activities (particularly television viewing and computer use), and shorter and fragmented sleep. However, it is important to note that no single factor among these has been shown to play a pivotal role in the increasing prevalence of obesity.

Tracking

"Tracking" describes the risk for a disease state persisting over time. In the case of obesity, there is a moderate risk of childhood obesity persisting into adulthood, and that risk increases if the child remains overweight as he or she grows older (Figure 37-1). As an example, in one population with a high frequency of obesity, there was substantial tracking within weight categories from late childhood (age 9–11) to young adulthood (19–35 years).[8] Tracking varied by gender and ethnicity: 73% of European-American women tracked within their weight category, while 49% of European-American men tracked. Among African-American participants, 60% of both men and women remained in the same weight category between childhood and adulthood.

A child's risk for having obesity in adulthood also depends on the weight status of his parents. An obese preschool-aged child has a 33% risk of becoming an obese adult if neither of his or her parents are obese, but an 83% risk if either parent is obese.[9] Before three years of age, the primary predictor of obesity in adulthood was the parents' obesity status, and the child's obesity status was not an important indicator of the risk of adult obesity. By contrast, after seven years of age, the child's own obesity status became the more important predictor of his or her risk for obesity in adulthood.

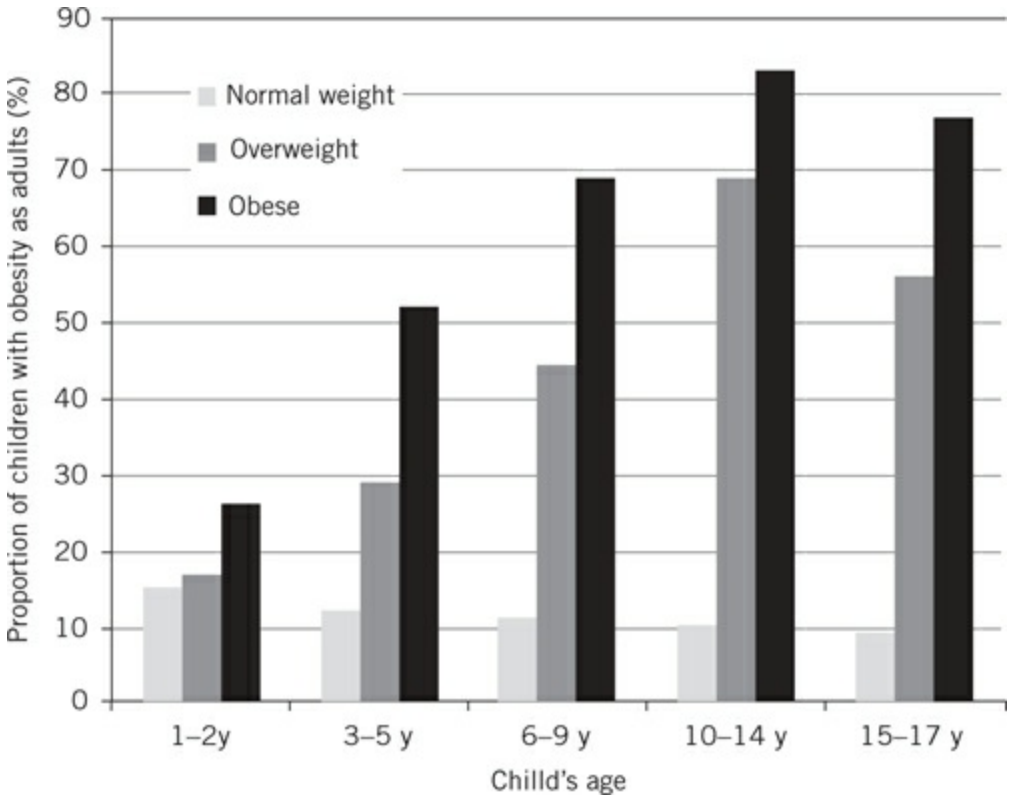

Figure 37-1 Tracking of obesity from childhood to adulthood. Proportion of children who will become obese as adults, as predicted by childhood weight status.[9]

Obesity in childhood thus confers a higher risk of obesity in adulthood. Moreover, adults who were obese in childhood have a greater risk of morbidity and mortality, independent of their BMI in adulthood, family history of cardiovascular diseases or cancer, and smoking.[10,11] In longitudinal studies, overweight adolescents were shown to have an increased risk for developing obesity-related medical problems in adulthood, including cardiovascular disease, diabetes, and breast cancer, as compared to adults with more recent onset of obesity.[12,13]

PATHOPHYSIOLOGY OF OBESITY

Heritability

Studies of twins and adoptees provide useful estimates of the role of heritable factors in determining an individual's body weight.[14] Adoption studies tend to generate the lowest heritability estimates (30%), whereas

twin studies provide highest heritability estimates (70%). The variability in estimates of heritability depends in part on definitions of obesity used in each study: more severe obesity tends to have a greater heritability factor than lesser variations in BMI.

Observations of a genetic contribution to obesity gave rise to the "thrifty genotype hypothesis,"[15] which posits that genes predisposing to energy conservation were preserved as a survival characteristic in times of famine, but become a liability in environments with plentiful food and low required physical activity. Possible mechanisms through which genetic polymorphisms can translate to differences in body weight regulation are discussed below.

Metabolic Programming

Several decades ago, David Barker and colleagues showed that poor fetal growth, resulting in *low* birthweight, is associated with an increased risk for type 2 diabetes and other elements of the metabolic syndrome. They proposed that poor nutrition during gestation imprints permanent changes in glucose and insulin metabolism.[16] Interestingly, many more recent studies have also shown clear associations between *high* birthweight and several components of the metabolic syndrome,[17] suggesting that newborns at both ends of the weight spectrum are at risk for obesity-associated disease. This concept of "metabolic programming" has now been supported by numerous studies in other human populations and in animals.

The metabolic programming hypothesis has been extended to include the possibility that postgestational influences can participate to create a lifelong metabolic phenotype.[18] For example, a study of adults in Finland showed that the development of type 2 diabetes mellitus was associated with the combination of low birthweight followed by accelerated gain in height and weight during childhood and with high maternal BMI.[19] Other studies have demonstrated an association between childhood weight gain and cardiovascular disease markers in adulthood.[20] Indeed, populations in transition from conditions of low-to high-nutrition may be at the greatest risk for such obesity-related complications because of the combination of fetal undernutrition and childhood overnutrition.[2]

A few studies strongly support the idea that the intrauterine environment affects obesity risk independently from genetic factors, thus distinguishing the concept of a "thrifty phenotype" from that of the "thrifty genotype." In a study of the effects of wartime famine in the Netherlands,

infants exposed to famine in utero had higher rates of obesity and diabetes in adulthood as compared to a genetically similar cohort not exposed to famine, and this effect was largely independent of birthweight.[21] Furthermore, the timing of the famine exposure during gestation appeared to have important effects, as fetuses exposed to famine during the first trimester of gestation were more severely affected than those exposed later in gestation. These observations are supported by animal studies, which also demonstrate lasting effects of intrauterine and postpartum nutrition. Other studies have shown that children of mothers who had undergone gastric bypass surgery prior to pregnancy have reduced risk of obesity as compared to the offspring of mothers who had not undergone the surgery.[22]

The mechanism underlying the observed associations, including the contributions of maternal hyperglycemia, insulinemia, and postnatal growth to the development of later complications, is an important subject for future studies. See Chapter 26, “Human Growth and Disease in Later Life,” for further discussion of the influence of the prenatal environment on obesity and other nutritional diseases.

Genetics

Mature animals and adult humans have a strong tendency to maintain a stable body weight over time, due to a close but sometimes imperfect matching of energy intake with energy expenditure. Animal studies in which energy intake is manipulated reveal powerful homeostatic mechanisms defending body weight. Similarly, the poor long-term results of weight reduction therapies in humans (about 95% of adults regain all weight after dieting), suggest there are mechanisms that defend a highly individualized “set point” for body weight. When an individual has a heritable or acquired susceptibility to positive energy balance, superimposed on these native homeostatic mechanisms, he or she has a tendency to become obese.

Currently, identifying specific genetic causes of obesity is rarely possible or useful during the course of clinical care, with the exception of the small minority of patients with syndromic obesity in whom understanding of the syndrome may inform clinical management. For example, identifying individuals with leptin deficiency allows for a specific and effective therapy, but this defect is extraordinarily rare (fewer than 10 individuals identified to date), so general screening for this disorder is not necessary or appropriate. These and other genetic causes of obesity are detailed below.

Nonetheless, a basic understanding of the genetic contributors to obesity is helpful in guiding the clinical evaluation of a patient. Furthermore, ongoing research in this field is rapidly expanding knowledge about the mechanisms underlying weight regulation and obesity. It is likely that some of these mechanisms will lead to better-targeted interventions, so that in the future, pharmacologic and/or behavioral interventions may be guided by an individual patient's genetic profile.

Common Obesity

The predisposition to obesity is a heritable trait, as outlined above. However, the specific genetic cause or causes of obesity cannot be determined for the vast majority of individuals with obesity. Genome-wide association studies have identified a variety of loci that contribute to obesity risk, including the fat mass and obesity-associated gene *(FTO)*, which is most strongly associated with obesity, conferring about 1.7-fold increased risk. Other loci are near genes that encode neuronal regulators of appetite or energy balance, including melanocortin 4 receptor *(MC4R)*, brain-derived neurotrophic factor *(BDNF)*, pro-opiomelanocortin *(POMC)*, and transmembrane protein 18 *(TMEM18)*.[23] Each of these loci contributes only a small increased risk of obesity. Thus, the genetic predisposition to common obesity is likely to be determined by a combination of multiple risk alleles acting in concert, including some that have yet to be discovered.

Monogenic Causes of Obesity

Genetic studies on individuals with very severe or early-onset obesity have identified specific mutations in genes known to be involved in the regulation of body weight. Mutations in MC4R are the most common of these; heterozygous mutations are present in 4% to 6% of individuals with early-onset obesity.[14] Individuals with MC4R mutations tend to have increased linear growth, hyperinsulinemia and normal cognition; hypertension is rare. A few individuals have been identified with homozygous or compound heterozygous MC4R mutations, and they have a more severe phenotype. Other genes with mutations that are strongly associated with obesity include *POMC*, leptin *(LEP)*, leptin receptor *(LEPR)* and proprotein convertase 1 *(PCSK1*, also known as prohormone convertase 1). These mutations are extremely rare, each identified in fewer than 20 individuals worldwide, most from consanguineous families (Table

37-1).

TABLE 37-1 Selected Monogenic Causes of Obesity

Gene	Characteristics
Melanocortin 4 receptor (MC4R)	4%–6% of individuals with early-onset obesity are heterozygous for an MC4R mutation. Hyperinsulinemia, hyperphagia, increased linear growth. Low prevalence of hypertension.
Leptin (LEP) or leptin receptor (LEPR)	Fewer than 20 cases of each reported, usually associated with consanguinity. Severe early-onset obesity, hyperphagia, hypogonadism.
Pro-opiomelanocortin (POMC)	Fewer than 10 cases reported. ACTH deficiency with adrenal crisis, early-onset obesity, red hair.
Proprotein convertase 1 (PCSK1)	Fewer than 10 cases reported. Low plasma insulin but high proinsulin; hypogonadotropic hypogonadism, diarrhea.

Obesity Syndromes

Approximately 30 human genetic syndromes whose phenotype includes obesity have been identified and cataloged in the Online Mendelian Inheritance in Man (OMIM) database, including Albright, Alström, Bardet-Biedl, Beckwith-Wiedemann, Carpenter, Cohen and Prader-Willi syndromes. Many of these syndromes have been mapped to one or more chromosomal locations.

The most common syndrome with severe obesity is Prader-Willi syndrome characterized by infantile hypotonia, hyperphagia, hypogonadotropic hypogonadism, and cognitive deficits. This disorder is caused by loss of paternally expressed genes in chromosome 15q11-13, a region containing several candidate genes for which mechanistic explanations for the Prader-Willi phenotype(s) are being sought.[24] The syndrome occurs in approximately 1 in 25,000 live births. Because the defect almost always arises sporadically, recurrence within a family is extremely rare. Interestingly, individuals with Prader-Willi syndrome also have elevated levels of ghrelin, providing a potential mechanism for their marked hyperphagia.

The Bardet-Biedl syndrome requires a mutation at one of 15 loci[14] and includes polydactyly and retinopathy. It is rare, occurring in less than 1 in 100,000 live births. Molecular studies suggest that the syndrome may be caused by loss of function of ciliated hypothalamic neurons. Alström syndrome (retinopathy, deafness, often with cardiomyopathy and renal

failure), and Cohen syndrome (hypotonia, retinopathy, and cognitive deficits) have been mapped to one location each, and candidate genes have been identified but the mechanism through which mutations in these genes causes obesity is still unknown. Each of these syndromes has characteristic findings as outlined in Table 37-2 and in the OMIM database (www.omim.org). These syndromes usually can be distinguished from common obesity by a thorough medical history and physical examination.

EVALUATION

Definitions of Obesity

Any definition of obesity is useful only if it predicts medical disability or complications. Since most medical complications of obesity are associated with excess body fat and not muscle mass, measures of obesity represent an attempt to estimate the adipose compartment. At present, there is no precise clinically practical method to measure body fat, so most metrics use measurements of body weight as a surrogate for adiposity. Such approaches are imperfect, as they may misclassify a patient with an unusual proportion of fat to lean body mass, but they are inexpensive and practical for use in the clinical setting and in epidemiological studies.

Current definitions of overweight and obesity rely on calculations of the body mass index (BMI), defined as the weight in kilograms divided by the height in meters squared (kg/m^2). Although BMI does not directly measure body fat, it has been established as a useful predictor of adiposity in adults, adolescents, and children. Like other estimates of adiposity, BMI is a moderately good predictor of risks for present or future medical complications of obesity.[25] BMI in children is not only correlated with other predictors of body fat but also with blood pressure, lipid levels, fatty liver disease, and markers of insulin resistance.

TABLE 37-2 Selected Genetic Syndromes With an Obesity Phenotype

Syndrome	Characteristics
Albright hereditary osteodystrophy (pseudohypoparathyroidism type 1a) (MIM #103580)	Short stature, skeletal defects, subcutaneous ossifications, impaired sense of smell, variable intellectual disability.
Alström (MIM #203800)	Retinopathy (causing early nystagmus and progressive blindness), neurosensory deafness, truncal obesity with insulin resistance. Often

	complicated by cardiomyopathy, renal or hepatic failure and pulmonary fibrosis.
Bardet-Biedl (MIM #209900)	Retinopathy, polydactyly or syndactyly, mild intellectual disability, hypogonadism, structural or functional renal disorders.
Beckwith-Wiedemann (MIM #130650)	Features are variable, but often include macrosomia +/-hemihypertrophy, macroglossia, ear creases, omphalocele or umbilical hernia, neonatal hyperinsulinemia and hypoglycemia; risk of embryonal tumors.
Cohen (MIM #216550)	Prominent incisors, microcephaly, moderate–to-severe intellectual disability.
Prader-Willi (MIM #176270)	Infantile hypotonia and feeding problems; intellectual disability, short stature, hypogonadism. Obesity usually develops in early childhood.

In adults, standard ranges of BMI can be used to define risk categories for obesity. However, during childhood and adolescence, BMI varies with age and gender. Therefore, BMI percentiles are used to define risk categories for children and adolescents, and BMI growth charts or standard deviation scores are used to track an individual against established standards for clinical purposes.

In 2000, the Center for Disease Control and National Center for Health Statistics (CDC/NCHS) established new growth charts using data from five large surveys representing the U.S. population.[26] These growth charts do not include data from the previous decade because of the sharp rise in BMI during that period. They are similar but not identical to those developed by the International Obesity Task Force (IOTF).[27] For the IOTF charts, data were drawn from six different countries, and the curves were smoothed to meet the adult cutoff points for overweight and obesity at 18 years of age. Both reference standards are strong predictors of obesity and coronary heart disease risk factors in adulthood.[28] In April 2006, the World Health Organization (WHO) released new growth curves for exclusively breastfed infants and young children. The WHO BMI curves cover a wider age range (from infancy through age 5 years), and provide different norms for children than the CDC/NCHS standards. On the WHO curves, the normal range is generally defined as between two standard deviations (SDs) below and above the mean, which corresponds approximately to the 2nd and 98th percentiles. The CDC now recommends use of the WHO curves for infants and children up to two years of age, and the CDC/NCHS curves for children and adolescents 2 years and older.[29] See Chapter 2, “Clinical Assessment of Nutritional Status,” for further

discussion of the derivation and applicability of these WHO standards.

BMI also varies with pubertal stage, reflecting changes in fat-free as compared to fat mass. In addition, there is some evidence that BMI varies with ethnicity. Therefore, research studies that aim for the most precise estimates of obesity risk using BMI should consider not only age and gender, but also pubertal stage and ethnicity. However, for clinical purposes, the WHO/CDC/NCHS or IOTF growth references are adequate for determining obesity-related risk groups.

Body Mass Index

The initial step for the assessment of the overweight child is to calculate the BMI from measured weight and height, then plot the result on standard BMI growth curves to determine the child's weight category.

By general consensus, weight categories in children between 2 and 18 years of age are defined by the following BMI ranges, for age and sex[27,30]:

- Underweight: BMI < 5th percentile
- Normal weight: BMI between the 5th and 85th percentiles
- Overweight: BMI between the 85th and 95th, or BMI ≥ 25 (whichever is lower)
- Obese: BMI ≥ 95th percentile, or BMI ≥ 30 (whichever is lower)
- Severe obesity: BMI ≥ 99th percentile.[12,30] An alternate definition of severe obesity is a BMI ≥ 120% of the 95th percentile values, or a BMI ≥ 35 (whichever is lower).[31]

Additional important information is derived from plotting serial values of BMI, to assess the child's growth trend. A child whose BMI has risen across two major percentile curves is at risk for becoming overweight or obese even if the current BMI does not yet fall into one of these categories. Similarly, a child whose BMI is in the obesity range but with a flat or decreasing trend is displaying an improvement in weight status relative to his or her peers.

Finally, it is valuable to determine the weight status of the child's biologic parents by documenting their measured or reported height and weight, and calculating their BMIs. This is because the child's long-term risk of obesity is strongly affected by the weight status of his or her parents. Assessment of the parents' weight status by visual impression is frequently inaccurate, even by experienced observers.

Medical Assessment

The two main goals of the medical evaluation of the overweight child is to (1) assess for specific causes of obesity, including medication-related weight gain and potential obesity-associated syndromes or endocrinopathies and (2) to diagnose possible comorbidities associated with obesity. The family history should assess obesity and related medical problems in first-and second-degree relatives, to help establish the genetic factors underlying the weight disorder, and the potential future medical risks.

Evaluating for Causes of Obesity

Syndromic obesity should be considered, but in most cases, these syndromes can be distinguished on the basis of their unique features (listed in Table 37-2 and described in more detail in the genetics section above).[14] Specific laboratory testing is valuable for confirmation of the diagnosis in children with suspicious clinical features of a syndrome, but is not appropriate for general screening of unselected patients. For Prader-Willi syndrome (PWS), a cognitive deficit and history of hypotonia during infancy are particularly strong predictors of the syndrome. The presence of these characteristics in a child with severe early-onset obesity is an appropriate indication for performing genetic testing for PWS, which is highly sensitive and specific.[24]

Endocrine causes of obesity are rare, and usually can be excluded by the clinical history and physical examination. Hypothyroidism tends to cause a delay in linear growth, and its contribution to weight gain is typically modest. Therefore, hypothyroidism is unlikely in a child with good linear growth and gradual onset of obesity. Similarly, Cushing's disease causes a marked delay in linear growth. It can cause substantial weight gain, usually abrupt in onset, as well as central fat distribution and a suprascapular fat pad. If Cushing's disease is suspected because of these clinical features, the most appropriate screening test is a 24-hour urine collection for free cortisol.

The medical history should include assessment of concomitant medical diseases for their potential to contribute to weight gain, such as a history of a brain tumor or significant head trauma that might cause hypothalamic dysfunction. A variety of drugs used for the treatment of psychiatric disease, epilepsy, diabetes, and migraines are associated with weight gain. The atypical antipsychotic drugs and mood stabilizers are particularly likely to promote weight gain. However, the weight-promoting effects of other commonly used classes of drugs, including tricyclic antidepressants, selective serotonin reuptake inhibitors, anticonvulsants, and antidiabetic

agents are less widely recognized. Identifying these as a likely trigger of weight gain may prompt consideration of alternate drugs (Table 37-3). There is limited empiric information about the weight-related effects of many psychoactive drugs, and their long-term effects on weight are particularly unclear. Most of these drugs should be considered potential contributors to weight gain even if they are said to be "relatively" weight neutral.

TABLE 37-3 Drugs that Promote Weight Gain

Atypical antipsychotics

Clozapine ++++
Olanzapine ++++
Risperidone ++

Mood stabilizers
Divalproex sodium +++
Lithium +++

Tricyclic antidepressants
Amitriptyline ++
Imipramine ++

Selective serotonin reuptake inhibitors (SSRIs)
Paroxetine ++
Sertraline +

Anticonvulsants
Valproate ++
Carbamazepine +
Gabapentin +

Antidiabetic agents
Insulin ++
Thiazolidinediones (rosiglitazone) +

Screening for Comorbidities

The pathophysiology of medical conditions related to obesity (Table 37-4) is discussed in Chapter 38, "The Metabolic Syndrome in Children and Adolescents," but the laboratory assessment of these conditions is discussed below.[30] Most guidelines recommend screening for dyslipidemia, steatohepatitis, and evidence of glucose intolerance, particularly as specific treatments for some of these disorders are increasingly considered.

Blood testing should be done in a fasting state if practical. Total cholesterol, very low-density lipoprotein, low-density lipoprotein, high-density lipoprotein, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) have been recommended to screen for possible

hypothyroidism, dyslipidemia, and steatohepatitis, respectively (Table 37-5).

The American Diabetes Association recommends screening for type 2 diabetes in children 10 years or older who are overweight or obese and have two additional risk factors (including clinical evidence of insulin resistance, a family history of diabetes, or member of a diabetes-prone ethnic minority).[32] Fasting or random glucose levels, or hemoglobin A1C (A1C) are used to screen for diabetes mellitus or increased diabetes risk (sometimes called "prediabetes") (Table 37-6).[30,32] A1C is particularly useful for screening because it does not require fasting. However, the accuracy of A1C as a screening test is not well established in adolescents. All of these screening tests lack both sensitivity and specificity for diagnosing type 2 diabetes or impaired glucose tolerance in children, so oral glucose tolerance testing should be used when possible in high-risk individuals. Fasting insulin levels are measured by some clinicians to provide information on carbohydrate metabolism and insulin resistance, but this test is not reliable for predicting risk for diabetes.

TABLE 37-4 Comorbidities of Obesity in Children

Endocrine
Type 2 diabetes
Polycystic ovary syndrome (PCOS)

Cardiovascular
Hypertension
Dyslipidemia
Ventricular hypertrophy, early atherosclerotic disease

Respiratory
Asthma
Obstructive sleep apnea

Gastrointestinal
Gastroesophageal reflux disease (GERD)
Fatty liver disease
Constipation and encopresis

Orthopedic
Slipped capital femoral epiphysis (SCFE)
Blount's disease

Neurologic
Pseudotumor cerebri

Psychologic
Depression, anxiety, social exclusion

Further laboratory testing may be useful in selected cases but can be

expensive and some tests are not readily available. Sleep studies can and should be performed if there are clinical symptoms of sleep apnea, including consistent snoring and/or nocturnal enuresis, especially in a child with severe obesity. Radiographic evaluation is necessary when slipped capital femoral epiphysis (SCFE) or Blount disease is suspected. SCFE usually presents with hip and/or knee pain, and Blount's disease with visible bowing of the knees and/or pain. Indirect calorimetry can be used to predict the energy deficit necessary for weight loss. This is not necessary for routine dietary counseling, but might be useful when poor compliance or abnormally low energy requirements are suspected and at times may be useful to provide concrete caloric goals to support dietary changes. Consultations with specialists in sleep disorders, neurology, otorhinolaryngology, pulmonology/allergy, endocrinology, genetics, ophthalmology, and surgery may be necessary to manage specific complications.

Nutritional Assessment

Nutritional evaluation should include a history of the onset of obesity, as well as of weight loss attempts. Assessing dietary intake by recalled food frequency does not provide a good estimate of energy intake, as underreporting of food intake by obese subjects is well described. However, it helps to evaluate diet composition, which may help identify targets for dietary change. In addition, the diet recall may be useful to assess the diet for deficiencies in micronutrients, particularly calcium and vitamin D, as well as vitamins A, E, β-carotene, folic acid, and other B vitamins; excessive energy intake does not always mean adequate intake of micronutrients.

TABLE 37-5 Laboratory Evaluation for Comorbidities of Obesity in Children and Adolescents

Laboratory Test	Indications
Lipid profile	All children with overweight or obesity (>10-year-old, repeat every two years)
Fasting glucose and/or Hemoglobin A1C	All children with overweight or obesity and two risk factors* (>10-year-old, repeat every two years)
Alanine aminotransferase (ALT) Aspartate aminotransferase (AST)	Generally recommended in children with obesity
Blood pressure (BP)	All children with overweight or obesity

Use an adequate sized cuff Interpret using age-based blood pressure norms	Prehypertension: BP 90–95th percentile or ≥120/80 mmHg Hypertension: BP ≥ 95th percentile or ≥140/90 mmHg
Sleep study (polysomnogram)	Moderate-severe obesity and any symptoms suggestive of sleep apnea (habitual snoring, mouth breathing, nocturnal enuresis)
Testosterone and Sex hormone binding globulin (SHBG) OR free testosterone	Girls with abnormal menses or hirsutism
Glucose tolerance test	If fasting glucose > 100, or Hemoglobin A1C > 5.7, or symptoms of diabetes
Depression screen	All children with obesity

* The American Diabetes Association recommends diabetes screening in children overweight children with two additional risk factors (including clinical evidence of insulin resistance, a family history of diabetes, or member of a diabetes-prone ethnic minority).

TABLE 37-6 Laboratory Assessment for Diabetes Mellitus

Test	Increased Risk for Diabetes (Prediabetes)	Diabetes Mellitus
Fasting plasma glucose	100–124 mg/dL (5.6–6.9 mmol/L)	≥ 125 mg/dL (7.0 mmol/L)
Random plasma glucose		≥ 200 mg/dL (11.1 mmol/L) with symptoms
Hemoglobin A1c	5.7%–6.4%	≥ 6.5%
Oral glucose tolerance test: Plasma glucose 2 hours after 75 g glucose load	140–199 mg/dL (7.8–11 mmol/L)	≥ 200 mg/dL (11.1 mmol/L)

To identify possible areas for intervention, the amount and type of dairy products, fruits, vegetables, and legumes should be assessed, with particular attention to the consumption of sugar-sweetened beverages including juices and soda. Excessive consumption of sugar-sweetened beverages or juice has been associated with excess weight gain and increased rate of obesity, and is an important early target for dietary change.[7,30,33] Similarly, the frequency of use of fast-food restaurants and of other restaurant meals should be examined, because these meals often contain excessive caloric content and set inappropriate standards for

portion size. The diet history should also explore usual meal patterns, with attention to whether there is regular skipping of meals (especially breakfast), binge pattern of eating, and the social context of meals, particularly if there are routine family dinners. Each of these factors may become a target for intervention to establish regular meal-based eating patterns.

Finally, the potential role of exercise and sedentary behaviors should be evaluated, with particular attention to determining the frequency of television and computer use. Several studies have suggested causal effects of television viewing on obesity, and the American Academy of Pediatrics recommends limiting television viewing to one to two hours per day.[30] Assessment and encouragement of moderate to vigorous physical activity (e.g., participation in sports programs) is essential. It is also worthwhile to inquiring about and encourage lifestyle exercise, in the form of outdoor play or regular walking (e.g., walking to school); this is often the main type of physical activity for young children or older children who are deconditioned.

Behavioral Assessment

The psychosocial complications of obesity are often subjective and difficult to measure in a standard fashion, but undoubtedly represent one of the greatest burdens of obesity in children and adolescents. In many cases, psychosocial issues are best understood as consequences of the disease, brought on by feelings of discouragement and criticism by family, peers, or self. In other instances, the psychological issues precede or exacerbate the obesity.[30] Regardless of the causality, it is important to acknowledge and assess these behavioral and psychological issues in each individual to best target treatment.

Depressive symptoms, anxiety, binge-eating disorder, decreased self-esteem, and problems with social interactions have generally been found more frequently in obese children and adolescents than in their lean peers. Negative psychosocial associations also persist into early adulthood, when obesity is associated with lower educational attainment and household income and lower rates of marriage, independent of baseline education and aptitude. Many of these problems can be attributed to the widespread and culturally entrenched bias against obese individuals in our society.[7,30]

Optimal assessment of the psychosocial issues contributing to and stemming from obesity in a particular patient has not been established, and varies greatly between centers and providers. Whether or not standardized

instruments are used, some effort should be made to assess mood, motivation, school and social performance, self-image, and eating attitudes and behaviors. It is also important to assess these issues in parents or close caretakers of the patient, because factors such as motivation, mood disorders, and eating disorders in a parent will have substantial impact on the child's attitudes, behaviors, and ability to respond to treatment. The family's financial resources and level of cognitive stimulation in the household also predict the development of obesity, and may also affect the family's ability to respond to treatment. Assessing the readiness of the patient and family for making lifestyle changes is an important foundation for patient-centered motivational counseling.

TREATMENT

Nutritional Therapy

Scientific study of interventions to prevent and treat obesity is challenging because of the many factors that influence weight gain, which often cannot be controlled or measured, and difficulty in standardizing interventions. Moreover, short-term interventions are of questionable relevance for this chronic disease, yet prolonged interventions are impractical and costly.

Nonetheless, the preponderance of evidence suggests that lifestyle interventions can have modest effects on weight status.[34] In general, the more effective interventions were multimodal (combining diet, physical activity, and/or behavioral modification), included the family (especially for younger children), and had a moderate or highly intensive schedule (at least 25 contact-hours). Moreover, younger children seem to be more likely to respond as compared with older children. The majority of studies do not provide long-term outcomes, and many issues such as optimal macronutrient composition of diets and strategies to change food preference have not been adequately studied.

As rates of obesity rise, obese children represent an increasing proportion of hospital inpatients. Whether or not the child is hospitalized for an obesity-related condition such as gallstones, diabetes, sleep apnea, or orthopedic problems, his or her nutritional needs must be considered. It is particularly important to recognize that the obesity is a chronic problem, and will not resolve by attempting weight loss acutely during the inpatient stay. Moreover, acute severe caloric restriction is inappropriate and can lead to metabolic problems including refeeding syndrome, even in children with adequate or excessive energy stores. Guidelines for nutritional care of

the obese adult inpatients have been developed,[35] but this issue has not been well examined in children. It may be appropriate to prescribe a modest reduction in caloric intake for obese inpatients, guided by indirect calorimetry or by calculations based on adjusted body weights, and using a stress factor that is appropriate to the child's condition. The inpatient stay may also present a valuable opportunity for nutritional education, and for engaging the patient and family in a therapeutic plan to address the obesity beyond the hospital stay.

Weight Goals

The goal of an intervention is to reach and maintain a healthy weight without affecting linear growth. An appropriate goal for children younger than 5 years of age who are overweight or obese is weight maintenance, which will lead to gradual reduction in BMI percentiles over time.[30] In this age category, only severely obese children (e.g., BMI ≥ 99th percentile) should target actual weight loss (up to 1 lb per month). For children 6 to 11 years of age who are obese, it is appropriate to target gradual weight loss (up to 1 lb per month for BMI 95–99th percentile, and up to 2 lb per week for BMI ≥ 99th percentile). For adolescents 12 to 18 years who are overweight, it is reasonable to target weight maintenance or gradual weight loss; for those who are obese or severely obese, weight loss of up to 2 lb per week is reasonable.

These weight targets are based on expert opinion, and may not be realistic for many patients. Some patients may respond better to more modest and achievable weight goals, which can be readjusted as the patient progresses.

Lifestyle Goals

Dietary recommendations for adults and children with obesity typically target a reduction in dietary fat and energy intake as a balanced, hypocaloric diet (characterized by less energy than required to maintain weight but not less than 1200 kcal [5040 kJ]/d).[33] Counseling for children with obesity generally focuses on diet quality and quantity, rather than specific caloric goals. Nonetheless, a general estimate of energy requirements and caloric goals may be helpful as an initial step in counseling. Estimated energy requirements (EER) for normal growth in healthy children without obesity and low activity are approximately 1000 kcal/d for children 1 to 3 years and increase to about 1500 kcals by 8 years of age (adding up to 300 kcal/d if the child has a high activity level). EER

for adolescents with low activity levels are approximately 2000 kcal/d for girls, and 2500–2800 kcal/d for boys (adding up to 600 kcal/d if the adolescent has a high activity level). Children with obesity will probably have energy requirements somewhat higher than these estimates, because their basal metabolic rate increases with body weight. However, use of the age-based EER is sufficient to provide a general estimate of the child's caloric needs.

For weight loss in obese adolescents, it is reasonable to target a caloric goal approximately 500 kcals less than the EER, but not less than 1200 kcal/d. For younger children with obesity, it is reasonable to target the EER itself. However, any caloric goal is approximate, and dietary counseling should be guided by monitoring the change in weight and BMI over time. Energy requirements in children with obesity are discussed in detail in Chapter 36.

Specific dietary goals include limiting beverages and foods with high caloric density and low nutritional value, including sugar-sweetened beverages, baked goods, and fried foods, while encouraging whole grains, fruits and vegetables.[30,33] Simple behavioral measures such as meal planning and label reading during grocery shopping are also generally encouraged to support the implementation of these nutritional guidelines. Strong evidence indicates that limiting television viewing and other recreational screen time helps to prevent or treat obesity. The mechanism has not been established, but may include reductions in caloric intake. Eating breakfast and having meals as a family are generally recommended, based on moderate-quality evidence that these behaviors are inversely associated with obesity. Moderate quality evidence indicates that physical activity helps to prevent or treat obesity if sufficient intensity and frequency is achieved; guidelines suggest promoting a variety of options for moderate-to-vigorous physical activity, including team/group, individual, lifetime and recreational forms. Ensuring adequate sleep time for children also is recommended because of associations between short or fragmented sleep and obesity, although a causal effect has not been established. Breastfeeding is encouraged because it may have a protective effect on the subsequent development of obesity, although the effect is now thought to be weak. Despite the uncertainty about the protective effects of breastfeeding and adequate sleep, these behaviors are recommended because of their other established benefits and low risk of harm.[7]

These general goals have been captured in patient-focused messaging, which typically includes the following elements[36]:

5—Five servings of fruits and vegetables daily
2—Less than two hours of recreational screen time daily
1—At least one hour of moderate-to-vigorous physical activity daily
0—Zero servings of sugar-sweetened beverages daily

Breastfeeding, ensuring adequate sleep, and monitoring BMI are sometimes added to the messaging scheme.

Specific Diets

The "traffic-light diet" is an example of a structured, balanced, hypocaloric diet in a simple format, and has been used effectively for preadolescent and preschool children, in combination with a variety of behavioral interventions.[33] It uses a simple color-coding scheme to categorize foods into categories for free consumption (low-density foods; "green"), moderate consumption (moderate-density and protein-containing foods; "yellow"), and very limited consumption (foods with high caloric density, and/or with high sugar or fat content; "red"). The prescribed caloric content of the diet is generally between 900 and 1300 kcal/d (3780–5040 kJ/d).

The Protein-Sparing Modified Fast diet (PSMF) provides high-quality lean protein while strictly limiting total calories. It has been used to treat severe obesity in a variety of settings including hospitalized patients and school-based interventions. This diet has been effectively used in settings where short-term weight loss is medically necessary, but there are no data to suggest that it reliably improves obesity in the long term.[33] The diet typically consists of 600 to 800 kcal/d, including 2 g/kg/d protein to a maximum of 100 g/d, with supplements to ensure recommended intake of vitamins and minerals for about 12 weeks. This is followed by a maintenance diet (balanced macronutrients, 1,200 kcal/d). A PSMF diet typically yields substantially more short-term weight loss than that achieved by less restrictive measures, but by 15 months follow-up, the weight loss achieved is similar to patients on a steady balanced hypocaloric diet. Potential complications of the PSMF include protein losses, hypokalemia, inadequate calcium intake, cholelithiasis, and intravascular volume depletion with orthostatic hypotension.

While the caloric content of a diet has been shown to relate to treatment success at one year, to date, there is little evidence to suggest that alterations in *specific macronutrients* yield long-term weight reduction.[7,33] A variety of popular diets have arisen around alterations of specific macronutrients, with or without limitations on total caloric intake.

Many of these show good short-term weight loss, but there is little evidence that they achieve long-term improvements in weight status in adult or pediatric populations, although individual patients may benefit. Several dietary approaches have focused on limiting carbohydrates, and in general, this approach has modest efficacy, which is similar to that achieved with low-fat diets at one year.[33,37] The most rigorously studied such diet emphasizes foods with a low glycemic index to reduce insulin release and excursions of blood sugar. A few studies have shown short-term decreases in weight, appetite, and some cardiovascular disease risk factors during a hypocaloric low-glycemic-index diet as compared with a hypocaloric low-fat diet in young adults.[38] However, other studies have not shown beneficial effects of targeting low-glycemic-index foods, and none have examined long-term outcomes of this type of diet.

The results of studies that focus on adult populations should be interpreted with caution, since there is compelling evidence that at least some “lifestyle” approaches to obesity are more effective in children than they are in adults.[39] Some dietary approaches might prove to have long-term results in children even if none can be demonstrated for adults.

Behavior Therapy

As discussed above, some interventions in childhood have demonstrated long-term improvement of obesity with 5 or 10 years follow-up, thus children appear to have a more consistent and durable response to therapy than adults in the same family, or adult populations in general.[34] The importance of including behavior therapy in the treatment of obesity in children has been demonstrated, at least in a family-based setting.[33] Although many interventions use combinations of dietary, exercise, and behavioral interventions, it is notable that the few studies showing long-term benefits have had a rigorous and structured behavioral component.

Commonly used behavioral techniques include self-monitoring of food intake and weight, modeling, positive reinforcement (praise or rewards), contingency management (certain behaviors are paired with predictable, reinforcing responses), and stimulus control (learning to avoid situations that are cues to overeat).[33,40] Some studies have tested specific elements of these behavioral techniques. These have shown superiority of family-focused over patient-focused treatment, of positive reinforcement over restrictive or critical approaches, and of frequent (daily) over less frequent (weekly) positive reinforcement. The value of problem-solving techniques, such as preplanning and relapse prevention, has not consistently been

shown. Thus, there is ample evidence to support the use of behavioral modification techniques in the treatment and possibly the prevention of obesity in children. By contrast, there is little data to support the use of behavior "micromanaging" techniques such as rate of eating and bite size.

Behavior therapy should be thought of as a tool to achieve long-term changes in diet and exercise. For example, the behavioral techniques typically are applied to specific lifestyle goals, such as reducing intake of sugar-sweetened beverages and increasing physical activity, as described in the previous section. Expert consensus suggests that reinforcement (praise or rewards) be applied to achievement of goals for healthy *behaviors*, rather than to weight goals.[30]

Success in behavior change is highly dependent on the motivational state of the patient and/or family. The technique of motivational interviewing has been applied with some success to encourage lifestyle changes for weight management.[7,40] This premise of this technique is that counseling will be most successful if it is tailored to the "stage of change" of the patient. If the patient or family has low interest in making lifestyle change, initial efforts should be focused on helping them examine their priorities and how their current behaviors support or undermine their priorities, rather than focusing on action.

Weight Loss Drugs

Many of the drugs used for the treatment of obesity in adults in the past were characterized by unproven claims, highly variable efficacy, or dangerous side effects. Nonetheless, the incomplete but growing understanding of the mechanisms underlying the homeostatic control of body weight and the increased rigor applied to clinical drug trials hold promise for the development and use of pharmacologic agents to treat this chronic disease. In the short term, drugs can be important for a patient whose medical condition requires acute weight loss. Drugs may also have a role in treating the chronic component of obesity, because the use of drugs to promote weight loss may keep an individual patient engaged in the "lifestyle" component of treatment. Thus, pharmacotherapy for obesity is not at odds with lifestyle-changing approaches. As increasingly specific drugs are developed, efficacy and safety improve, and pharmacotherapy may ultimately be an essential tool to treat an otherwise refractory and devastating disease. Whether pharmacologic treatment is cost-effective depends in large part on whether it prevents the medical complications of obesity and associated costs of medical care.

Current options for the pharmacologic treatment of obesity are quite

limited, and any pharmacologic intervention should be paired with a rigorous and simultaneous lifestyle intervention.

Orlistat (Xenical®) is the only drug approved by the US Food and Drug Administration (FDA) for treating obesity in adolescents (ages 12 to 16 years). It acts by inhibiting gastrointestinal lipases, reducing fat digestion and absorption by about 30%. Its utility is limited by very modest efficacy (BMI after treatment 0.9 kg/m^2 less than placebo), frequent dosing (three times daily), and gastrointestinal side effects (oily stools or abdominal pain in up to 50% of patients).[41] Weight regain typically occurs upon discontinuation of the medication. Concurrent efforts to reduce energy intake and increase exercise are important.

Metformin improves insulin sensitivity and also promotes modest weight loss in adults and adolescents.[41] By contrast to other diabetic agents, metformin does not increase insulin secretion, but decreases hepatic glucose production and improves insulin sensitivity in both diabetic and nondiabetic individuals. It has very modest weight-reducing effects, yielding up to 3 kg/m^2 more weight loss than placebo in adherent patients. There is some evidence that metformin may be useful in ameliorating psychotropic drug-induced weight gain; in a meta-analysis of trials in adolescents with antipsychotic drug-induced weight gain, metformin yielded a 4% reduction in body weight.[42] Metformin is approved by the FDA for treatment of type 2 diabetes mellitus and is a first-line agent for adolescents with this disease. Use of metformin for treatment of prediabetes or obesity is off-label; given its very modest weight-reducing effects, its use for these conditions is questionable.

Methylphenidate and similar stimulants used for attention-deficit disorder are having increased dopaminergic tone, which tends to blunt appetite. However, the effects of these drugs on appetite tend to be short-term, the effects on weight are inconsistent and poorly studied, and may vary by patient population.[41] For example, one study showed no effect of methylphenidate on appetite among obese adult males. Moreover, these drugs have multiple adverse side effects including agitation, insomnia, tachycardia, and hypertension. Therefore, they are not recommended or FDA-approved for weight loss, despite their utility for treating attention deficit disorder in children and adults.

Phentermine, diethylpropion, phendimetrazine, and benzphetamine are noradrenergic agents with appetite-suppressant effects that have been studied and approved only for adult patients and for short-term use (12 weeks or less).[41] These drugs are considered to have some potential for

abuse and are listed on schedule III or IV of the Drug Enforcement Agency. They are not recommended or FDA approved for weight loss in children and adolescents, because of their substantial side effects, including potential for abuse.

Topiramate is an anticonvulsant drug that enhances signaling of gamma-aminobutyric acid (GABA), an important inhibitory neurotransmitter of the central nervous system. In a randomized dose-ranging trial in adults with obesity, the average weight loss among patients treated with topiramate was 2.2 to 5.8 kg or 0.9 to 1.9 kg/m^2 (among study completers).[43] The proportion of subjects losing 10% or more of their body weight was 16% to 29% among those treated with topiramate, versus 7% among those treated with placebo. Thus, topiramate appears to have modest but clinically significant weight-reducing effects. However, its use is limited by side effects, including difficulty with concentration, memory and cognition, psychomotor slowing, mood changes with nervousness, anxiety, and depression. It is not recommended or FDA-approved for weight loss in children and adolescents.

In 2012, a combination of phentermine and topiramate (Qsymia®) was approved by the FDA for weight loss in obese adults. In a one-year clinical trial, the combination drug yielded 10.2 kg weight loss on the higher dose of drug, versus 1.4 kg with placebo.[44] In addition to the cognitive and psychological side effects of topiramate noted above, concerns were raised about teratogenicity and increases in resting heart rate, leading to a "risk evaluation and management strategy" (REMS) that was mandated with the FDA approval.[45] No trials of phentermine-topiramate have been performed in pediatric populations. Thus, it is not recommended or FDA-approved for weight loss in children and adolescents.

Weight Loss Surgery

During the past 25 years, surgically induced weight loss has emerged as an important option for adults with severe obesity. In contrast to poor long-term success rates for nonsurgical treatments of obesity, surgical approaches generally produce durable and substantial weight loss. In large series of adults undergoing weight loss surgery, the mean reduction in excess body weight was 67%, corresponding to a 34% reduction in BMI.[46] The weight loss typically was maximal around one year postoperatively, followed by modest weight regain, then stable weight for up to 16 years of follow up. Diabetes, dyslipidemia, hypertension, sleep apnea, and other weight-related comorbidities resolved or improved substantially, and

mortality risk was reduced by 89% at five years postoperatively. Weight loss and comorbidity outcomes in adolescents appear to be similar to those in adults, although long-term follow up data are sparse in the adolescent population.[47]

The three most common operations performed today are the Roux-en-Y gastric bypass (RYGB), laparoscopic adjustable gastric banding (LABG), and laparoscopic sleeve gastrectomy (LSG) (Figure 37-2). Each of these procedures reduces gastric capacity, but RYGB and LSG also reduce appetite through entero-endocrine mediators. Weight loss outcomes are generally better for RYGB and LSG as compared with LAGB, and LAGB also requires periodic readjustment of pressure to produce an optimal effect. LAGB and LSG have somewhat fewer complications in the immediate postoperative period as compared with RYGB. However, LAGB also has a high rate of re-operation for complications including band slippage (as high as 25% in some series). About 10% of patients undergoing RYGB have important complications, which include dumping syndrome, anastomotic strictures or ulcers, internal hernias, kidney stones, episodic hypoglycemia, and gallstone formation requiring cholecystectomy.[46] Anastomotic leaks, staple-line disruptions, and pulmonary embolism can occur but have been reduced to 1% to 2% each by modifications in surgical technique and postoperative care.

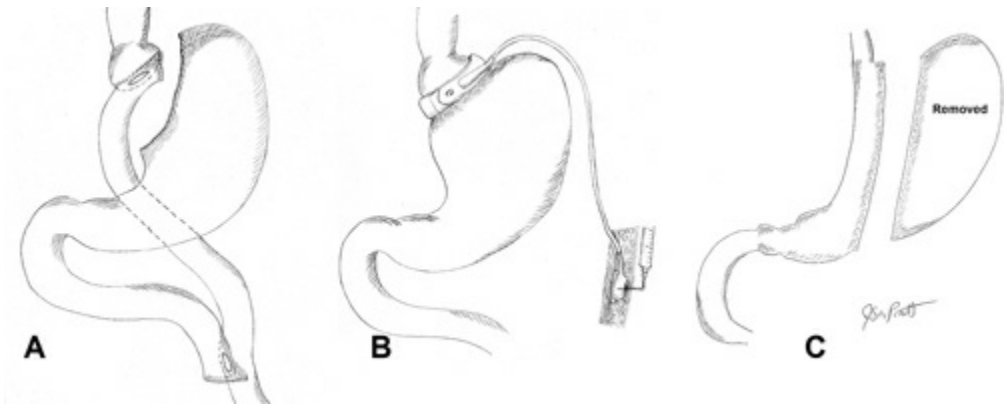

Figure 37-2 Types of weight loss surgeries. *PANEL A:* Roux-en-Y gastric bypass (RYGB). *PANEL B:* Laparoscopic adjustable gastric banding (LAGB). *PANEL C:* Laparoscopic vertical sleeve gastrectomy (LSG).

Patient Selection

The weight loss surgical procedures outlined above clearly have benefits that outweigh the modest risks for appropriately selected patients. Nonetheless, there is still some uncertainty regarding optimal patient selection. To date, no psychological or physiological factors have been defined that will determine which patients are most likely to suffer weight regain, medical complications, or psychological complications after weight loss surgery.

Currently, most guidelines suggest the following weight thresholds for selecting either adolescents or adults for weight loss surgery[48]:

- BMI ≥ 35 with major medical comorbidities (such as severe sleep apnea, type 2 diabetes, severe and progressive fatty liver disease, or pseudotumor cerebri).
- BMI ≥ 40 with more minor medical comorbidities (such as mild sleep apnea, dyslipidemia, hypertension, or impaired glucose tolerance). This threshold effectively selects for severe obesity among adolescents, because it is well above the 99th BMI percentile curve for all ages. Moreover, it is a more stringent selection criteria in younger as compared with older adolescents.

The guidelines also suggest the following additional considerations for selecting adolescents for weight loss surgery:

- Physical maturity—Demonstrated by completion of 95% of skeletal growth, or sexual maturity (Tanner) stage IV. Despite this guideline, it should be recognized that for some younger patients with serious complications of obesity, the benefits of surgery may still outweigh the small risk that the surgery might attenuate linear growth.
- Psychological and emotional maturity—Demonstrated by clear understanding of the risks and benefits of surgery, mature motivations for undergoing the procedure, and good compliance with preoperative therapy.
- Stable mental health—Psychological disorders should be fully evaluated and stabilized before consideration of weight loss surgery. Patients with substance use disorders can be considered on a case-by-case basis after they have been in remission for one year.

These represent the minimum considerations when evaluating an adolescent for weight loss surgery. Many other factors may enter the decision, including family and other support systems, adequacy of efforts

to improve weight status through non-surgical means, and the timing of the elective surgery relative to life events.

Nutritional Considerations

None of these surgical procedures causes significant malabsorption of dietary *macronutrients* or energy. However, it is very important to monitor patients postoperatively to ensure good dietary balance and to reduce the risk of vitamin deficiencies and protein malnutrition. Ample intake of fluids (e.g., 90 ounces daily) is encouraged to avoid dehydration, particularly in the early postoperative period. Most patients will also need to avoid sugar-sweetened beverages and other concentrated carbohydrates, to optimize weight loss and avoid dumping syndrome.[49]

Malabsorption of certain *micronutrients*, particularly iron, vitamin D and vitamin B_{12}, is common and requires postoperative monitoring and treatment. Case reports have described clinical vitamin deficiencies after weight loss surgery, of thiamine (vitamin B_1) causing beriberi, vitamin C causing scurvy, and of pyridoxine (vitamin B_6) causing pellagra. Deficiencies of zinc, selenium and copper are less well documented. Guidelines generally recommend supplements consisting of a multivitamin with iron, with additional vitamin D and calcium, and many programs also routinely supplement with vitamin B_{12}.[49] In addition, it is important to routinely monitor hemoglobin, iron, vitamin B_{12}, thiamine, and 25-hydroxyvitamin D after weight loss surgery, and provide additional supplementation as needed. Some guidelines also suggest monitoring pyridoxine, folic acid, vitamins A, C and E, zinc and magnesium. These nutritional concerns are most important for patients who have had RYGB, because the procedure bypasses some of the absorptive portion of the small intestine. Nonetheless, the same supplementation and monitoring usually is recommended for patients undergoing LAGB and LSG.

In female patients with regular menses, the risk of anemia is high, so it is common to recommend suppression of menses with hormonal contraceptives. Pregnancy is discouraged for the first 12 to 18 months after weight loss surgery, representing the phase of active weight loss. Outcomes of pregnancy after this period are typically good: pregnancy after weight loss surgery carries fewer risks for both the mother and the fetus than pregnancy in women with severe obesity (BMI $\geq$ 40). Female patients who become pregnant can continue their regular vitamin supplements, but should be monitored carefully for development of

anemia.

Future Directions

With the exception of surgery, current treatments for established obesity have disappointing long-term outcomes. However, research is likely to lead to advances in several important arenas. First, public recognition of the obesity problem should lead to public education and public programs designed to prevent obesity during childhood. Such population-wide approaches are more likely to be effective than treatment approaches targeting individual patients with therapies that are weakly effective and resource-intensive. The identification of which preventative strategies will be most effective is important before they can be implemented widely. Second, improved understanding of the genetic determinants and neural pathways underling the homeostatic control of body weight is likely to lead to pharmacologic interventions that are more specific, and therefore safer and more effective. Third, rigorously scientific and detailed analysis of specific environmental factors contributing to obesity, including issues of diet composition and meal patterns, may lead to more focused and effective dietary and behavioral interventions to treat obesity. Finally, education of the public and healthcare community to recognize and reverse the commonly held bias against obese individuals should help to minimize the stigma and psychological burden associated with the disease.

The Metabolic Syndrome in Children and Adolescents

38

Martin Wabitsch, MD, PhD

INTRODUCTION

The coincidence of the risk factors *visceral obesity, hypertension, dyslipidemia, insulin resistance,* and possibly *disturbed glucose regulation* in an individual is associated with a significantly increased risk of the occurrence of cardiovascular disease and type 2 diabetes mellitus as well as with an increased mortality. Longitudinal studies have shown that the occurrence of these risk factors in childhood and adolescence leads to an early onset arteriosclerosis. The clinical manifestation of arteriosclerosis, however, can only be recognized in advanced state. Clinical symptoms occur usually only in marked stenosis (>70%) of the coronary arteries or of the cerebral or leg arteries. Before the manifestation of the arteriosclerosis can be shown clinically, there are usually subclinical modifications of the vessels for many years, which are manifested as endothelial dysfunction, fatty streaks, swelling of the intima and media as well as plaques.

For many years, it has been recognized that several risk factors occur more than coincidentally together and can cause diseases like myocardial infarction and stroke. Nevertheless, the term metabolic syndrome (MetS) has found its way into clinical medicine only in recent years and was only recently established in the pediatrics and adolescent medicine.[1,2]

In the 1950s, Jean Vague recognized that the co-occurrence of obesity with abdominal body fat distribution, hypertension, diabetes, and gout

leads to arteriosclerosis. The American diabetologist Gerald M. Reaven described in 1988 the so-called syndrome X, a finding complex consisting of insulin resistance, hyperinsulinemia, hypertriglyceridemia, reduced high-density lipoprotein (HDL)-cholesterol, hypertension, and disturbed glucose tolerance. Finally, Kaplan spoke memorably about a "deadly quartet" consisting of abdominal obesity, hypertension, impaired glucose tolerance, and hypertriglyceridemia. The MetS was characterized in 1991 in pediatrics and adolescent medicine and was examined and discussed afterward by physicians of national and international pediatric societies.[3]

DEFINITIONS

The symptom complex consisting of obesity with abdominal body fat distribution, dyslipidemia (hypertriglyeridemia, reduced HDL-cholesterol), insulin resistance, and impaired glucose tolerance as well as arterial hypertension is known in adults as the MetS.

The corresponding symptoms occur in individuals more than coincidental in combinations ("clustering"). A similar constellation of risk factors can already be found in obese children.

Additional typical findings associated with MetS, which can occur in adolescence, are nonalcoholic fatty liver disease, hyperuricemia, and polycystic ovary syndrome, as well as microalbuminuria.

Interestingly, a clustering of cardiovascular risk factors is also often observed in other family members. In the parental and grandparental generations, secondary complications or endpoints (early onset myocardial infarction, stroke) may be present. This information about the family history is important for the assessment of the health risk of the affected child or adolescent.

The term "tracking," which is often used in relation with MetS, means the persistence of the individual risk factors from childhood to adulthood as well as an increasing expression of the risk factors with age. These correlations can be interpreted as follows: if evidence for MetS is found in one patient, these symptoms will persist quite likely in later life and the individual's clinical symptoms will develop with age. An exception is insulin resistance, which is more common in adolescence than in young adulthood.

So far, there is no generally accepted definition for MetS in childhood and adolescence with an indication for limit values for the individual components. The goal of developing a definition for the MetS in childhood and adolescence, which will have high clinical relevance, is barely

accessible at the moment. The reason is that a health risk for MetS has yet to be described, and there are insufficient long-term data to help us define individual reference values and their combination to match a prognostic risk. Beyond that, in childhood and adolescence it is not possible to indicate reference values for the individual components of MetS based on the development of these components that depend on age and puberty.

In 2007, the International Diabetes Federation (IDF) has published a proposal for a definition of the MetS in childhood and adolescence (Table 38-1). This rather conservative definition of MetS for childhood and adolescence is easily applied in practice and takes into account the developmental aspects (tracking). Until better definitions of MetS are available, the IDF definition of MetS for childhood and adolescence is proposed for use in practice.

TABLE 38-1 Consensus Definition of the Metabolic Syndrome in Childhood and Adolescence of the International Diabetes Federation (IDF)

Age 6 to <10 years

- Obesity > 90th percentile as assessed by waist circumference
- Metabolic syndrome cannot be diagnosed, but further measurements should be made if family history of metabolic syndrome, type 2 diabetes mellitus, dyslipidemia, cardiovascular disease, hypertension, or obesity
- IDF suggests that a strong message for weight reduction should be delivered for those with abdominal obesity

Age 10 to <16 years

- Obesity > 90th percentile (or adult cut-off if lower) as assessed by waist circumference
- Triglycerides > 1.7 mmol/L
- HDL-cholesterol < 1.03 mmol/L
- Blood pressure > 130 mm Hg systolic or >85 mm Hg diastolic
- Glucose > 5.6 mmol/L (oral glucose tolerance test recommended) or known type 2 diabetes mellitus

Age > 16 years

Use existing IDF criteria for adults.
According to the new IDF definition, for a person to be diagnosed with MetS, he or she must have:
Central obesity (defined as waist circumference with ethnicity-specific values) plus any two of the following four factors:

- Raised TG level: >150 mg/dL (1.7 mmol/L), or specific treatment for this lipid abnormality
- Reduced HDL cholesterol: <40 mg/dL (1.03 mmol/L) in males and <50 mg/dL (1.29 mmol/L) in females, or specific treatment for this lipid abnormality
- Raised blood pressure: systolic BP > 130 or diastolic BP >85 mm Hg, or treatment of previously diagnosed hypertension
- Raised fasting plasma glucose (FPG): >100 mg/dL (5.6 mmol/L), or previously diagnosed type 2 diabetes (if above 5.6 mmol/L or 100 mg/dL, OGTT is strongly recommended but is not necessary to define presence of the syndrome).

If BMI is >30 kg/m², central obesity can be assumed and waist circumference does not need to be measured.

TABLE 38-1B Upper Limits for Waist Circumference With Ethnicity-Specific Values

Country/Ethnic Group		Waist Circumference
Europids[a] In the United States, the ATP III values (102 cm male; 88 cm female) are likely to continue to be used for clinical purposes	Male Female	>94 cm >80 cm
South Asians Based on a Chinese, Malay, and Asian-Indian population	Male Female	>90 cm >80 cm
Chinese	Male Female	>90 cm >80 cm
Japanese[b]	Male Female	>90 cm >80 cm
Ethnic South and Central Americans		Use South Asian recommendations until more specific data are available.
Sub-Saharan Africans		Use European data until more specific data are available.
Eastern Mediterranean and Middle East (Arab) populations		Use European data until more specific data are available.

Children younger than 6 years were excluded from the definition because of insufficient data for this age-group.

[a]In future epidemiological studies of populations of Europid origin, prevalence should be given using both European and North American cut-off points to allow better comparisons.

[b]Subsequent data analyses suggest that Asian values (male 90 cm; female 80 cm) should be used for Japanese populations until more data are available.

The assessment of the cardiovascular risk in children and adolescents with reference for the presence of MetS and possibly the indication of a therapy should be stratified—independent of an exact specification for the definition of MetS.

REFERENCE VALUES FOR THE INDIVIDUAL COMPONENTS OF MetS

The German working group of obesity in children and adolescents recommends in their guidelines[4] the use of the following reference values for the diagnostic assessment of cardiovascular risk factors, which are conjunct in the MetS.

Visceral Obesity

In accordance with several national and international guidelines, obesity is defined by the reference values for body mass index (BMI). An assessment of abdominal fat distribution can be made by measuring the waist circumference. For this, the patient should be lightly dressed (in underwear), upright, standing straight view. Arms hanging sideways to the body and the body weight is evenly distributed on both legs. The patient should inhale and exhale quietly. For the measurement (measuring accuracy ± 1 mm), a nonelastic measuring tape is applied in the area of the strongest medial indentation of the body side structure between the lower costal arch and the iliac crest. If an indentation of the waist region is not recognizable, the waist circumference should be measured between iliac crest and costal arch. The measuring tape is applied horizontally to the ground and under tension (not denting the abdominal wall), the measured value is read after expiration of breath by the patient. To minimize errors, the measurement should be repeated, and the mean value should be calculated from the two measurements.

Waist circumference is also subject to age—and gender-specific alterations. In 2008, Kromeyer-Hauschild et al[5] have published age-and gender-specific percentiles for waist circumference of 6-to 18-year-old German children and adolescents (Figures 38-1A and B). In adults, an abdominal obesity with a waist circumference ≥80 (female) and ≥94 cm (male) is defined.[6] In contrast, there is no uniform value limit determination in the literature for children and adolescents. The waist circumference and the BMI are highly correlated.[5] To identify increased abdominal fat accumulation in childhood and adolescence, a waist

circumference above the 90th percentile is recommended based on the definition of obesity in children and adolescents (BMI > 90th percentile[7]).

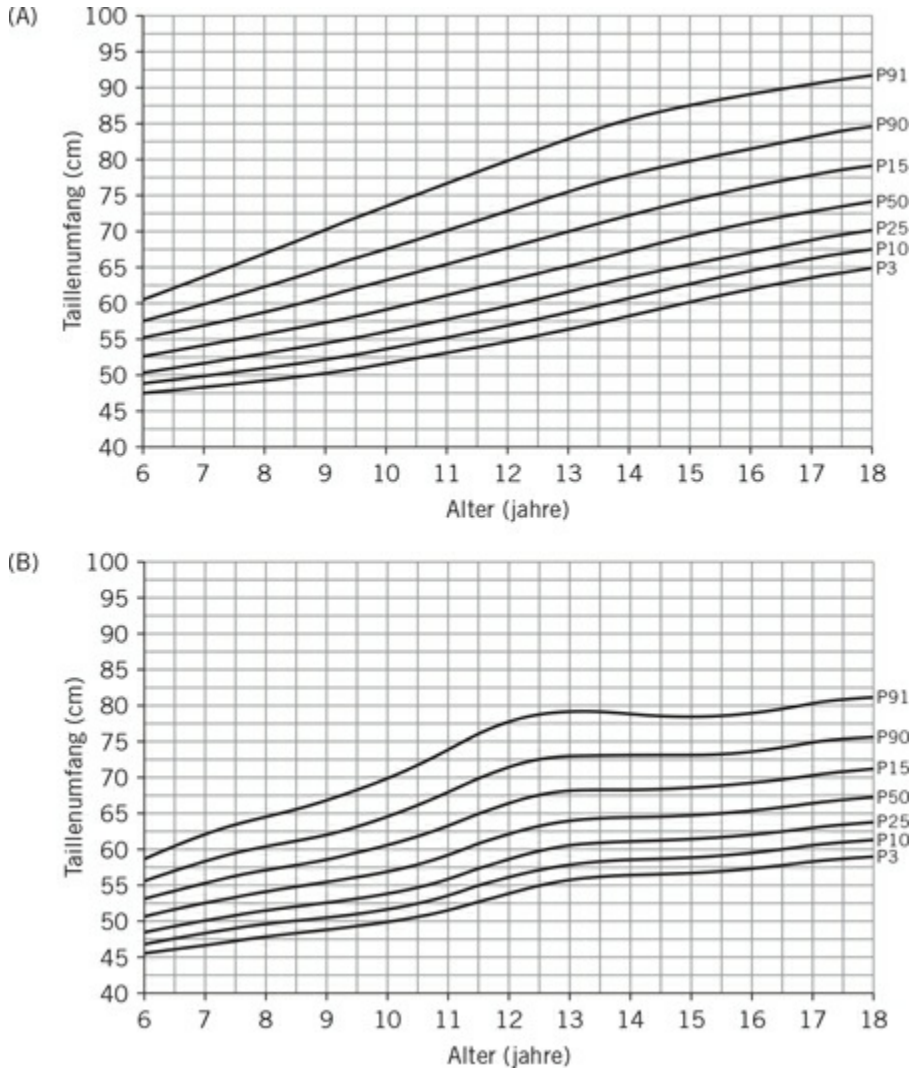

Figure 38-1 A, Percentile graph for waist circumference (boys 6–18 years) by Kromeyer-Hauschild et al.[5] B, Percentile graph for waist circumference (girls 6–18 years) by Kromeyer-Hauschild et al.[5]

Dyslipidemia

The determination of a fasting lipid levels (total cholesterol; low-density lipoprotein [LDL], HDL, triglycerides) is part of the basic diagnostic for all obese children and adolescents as well as overweight children and adolescents with special anamnestic risk factors, for example, a positive family history for early cardiovascular disease. Reference values are

available for the diagnostic evaluation of the lipid levels (Table 38-2).

Values outside of the desirable range should be observed in their further development of the patient. The assessment of the altered lipid values can only occur by taking into account of all cardiovascular risk factors. Any necessary dietary or pharmacological interventions should be made in accordance with the guidelines of the American Academy of Pediatrics.

Arterial Hypertension

The blood pressure measurement should be made in an upright sitting position, on the right arm in a quiet environment after a 5-minute period of rest. It is important to use the correct cuff width (one that covers at least 80% of the upper arm length). The measured values must be interpreted on the basis of sex-, age-, and height-specific reference values (examples of reference values are given in Tables 38-3A and B). The classification of hypertension in children and adolescents with measurement frequency and therapy recommendations is shown in Table 38-4.

With unclear or marginal results and in confirmation of the diagnostic of an arterial hypertension a 24-hour blood pressure measurement may be performed. The assessment of the 24-hour blood pressure measurement is also based on appropriate reference values.

Insulin Resistance and Glucose Regulation Disorder

An often clearly recognizable clinical indication for hyperinsulinemia is acanthosis nigricans, a dirty-brownish hyperpigmentation of the skin along with a coarsening of skin appearance, which typically occurs in the neck and armpits (Figure 38-2).

The determination of fasting serum insulin concentration allows calculation of insulin resistance indices (e.g., homeostasis model assessment of insulin resistance or quantitative insulin sensitivity check index); for calculation, see the guidelines of the German Working Group on Childhood Obesity (AGA).[4] Values outside of the desirable range should be followed during the further development of the child. It must also be considered that the method for insulin determination has not yet been standardized. The gold standard for the measurement of insulin resistance is the euglyemic-hyperinsulinemia clamp, a time-consuming, invasive, and expensive method, which is only suitable for scientific research.

The recommendations of the American Diabetes Association should be

applied to children and adolescents from age 10 or at onset of puberty (whichever comes first) to 19 years to screen for type 2 diabetes (see www.diabetes.org).

ETIOLOGY AND PATHOGENESIS

A strong genetic predisposition exists for the manifestation of individual components of MetS and for MetS itself. Table 38-5 shows estimated figures for heritability of the individual components. This genetic predisposition is polygenic and is because of polymorphisms in different genes. A single modification may thereby have a very small effect, and only the combination with further polymorphism leads to phenotypic changes. A systematic literature search with following meta-analysis identified eight polymorphisms, which are associated with MetS. These varieties were found in the following genes: *FTO*, *TCF7L2*, *IL-6*, *APOA5*, *APOC3*, and *CETP*.[8] All these polymorphisms were also associated with individual components, for example, insulin resistance. Twin studies have shown that approximately half of the variance in insulin sensitivity and secretion may be attributed to genetic factors.

TABLE 38-2 Acceptable, Borderline-High, and High Plasma Lipid, Lipoprotein, and Apolipoprotein Concentrations for Children and Adolescents According to the American Academy of Pediatrics (see www.aap.org)

Category	Low mg/dL[a]	Acceptable mg/dL	Borderline-High mg/dL	High mg/dL[a]
TC	—	<170	170–199	≥200
LDL cholesterol	—	<110	110–129	≥130
Non-HDL cholesterol	—	<120	120–144	≥145
Apolipoprotein B	—	<90	90–109	≥110
Triglycerides				
0–9 y	—	<75	75–99	≥100
10–19 y	—	<90	90–129	≥130

HDL cholesterol	<40	>45	40–45	—
Apolipoprotein A-1	<115	>120	115–120	—

[a]Low cut-off points for HDL cholesterol and apolipoprotein A-1 represent approximately the 10th percentile. The high and borderline-high cut-off points represent approximately the 95th and 75th percentiles, respectively.

Insulin Resistance As Central Pathomechanism of MetS

The central pathogenetic feature to the MetS is insulin resistance. The term insulin resistance refers to a reduced glucose uptake of the whole body in response to physiological insulin levels. Insulin resistance has an inverse relation to insulin sensitivity. Euglycemic hyperinsulinemia clamp studies showed that insulin resistance is especially determinated by the insulin response of the skeletal muscle (more than 75% of the amount of glucose during the test is absorbed from muscle and only 2%–3% from adipose tissue). Nevertheless, the adipose tissue has an important function especially with increasing fat mass (see below). Insulin resistance typically occurs in obesity with abdominal body fat distribution, where the visceral fat mass is increased.

In pediatrics and adolescent medicine, it is important to note that during adolescence a physiological insulin resistance of the body is observed. During adolescence, you will find a 25%–50% decrease in insulin sensitivity of the body to return to normal after the end of adolescence.

From epidemiological studies, it is also known that individuals who were born to mothers with poorly controlled diabetes mellitus or gestational diabetes or who were born as small-for-gestational-age babies showing increased weight gain during infancy tend to develop insulin resistance later in life. Epigenetic mechanisms are very likely to come into play (the principle of fetal programming) (see Chapter 27).

The Molecular Basis of Insulin Resistance in MetS

Insulin mediates its effect on the target organs via specific membrane receptors.[9] The insulin receptor consists in an extracellular α-subunit and two transmembrane β-subunits, which are linked by disulfide bonds. The binding of insulin to the α-subunit results in a change of three-dimensional receptor structure (conformation), which causes autophosphorylation of β-subunit. Receptor activation leads to phosphorylation of insulin receptor substrate proteins (IRS-proteins), which are in turn coupled to another kinase, phosphoinositide-3-kinase (PI3-kinase, PI3K). This lipid kinase phosphorylates the signal substance phosphatidylinositol biphosphate into phosphatidylinositol triphosphate, which ultimately enables the central kinase of the insulin signal transmission Akt. The insulin signal is now

passed on to the various effector cells. Thus, the uptake of glucose into the cell through the glucose transporter-4 (Glut-4), or glycogen synthesis, is activated.

TABLE 38-4 Classification of Hypertension in Children and Adolescents With Measurement Frequency and Therapy Recommendations

	SBP or DBP Percentile[a]	Frequency of BP Measurement	Therapeutic Lifestyle Changes	Pharmacolc Therapy
Normal	<90th	Recheck at next scheduled physical examination	Encourage healthy diet, sleep, and physical activity	—
Prehypertension	90th to <95th or if BP exceeds 120/80 even if <90th percentile up to <95th percentile[b]	Recheck in 6 mo	Weight-management counseling if overweight; introduce physical activity and diet management[c]	None unless compelling indications suc chronic kidney disease, diabet mellitus, heart failure, or left ventricular hypertrophy (L exist
Stage 1 hypertension	95th–99th percentile plus 5 mm Hg	Recheck in 1–2 wk or sooner if the patient is symptomatic; if persistently elevated on 2 additional occasions, evaluate or refer to source of care within 1 mo	Weight-management counseling if overweight; introduce physical activity and diet management[c]	Initiate therapy hypertension persists despite trial of four to s months of nonpharmacolc therapy or if compelling indications (as shown above)
Stage 2 hypertension	>99th percentile plus 5 mm Hg	Evaluate or refer to source of care within 1 wk or immediately if the patient is symptomatic	Weight-management counseling if overweight; introduce physical activity and diet	Initiate therapy

	management[c]

[a]For gender, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value.

[b]This occurs typically at 12 years old for SBP and at 16 years old for DBP.

[c]Parents and children trying to modify the eating plan to the Dietary Approaches to Stop Hypertension Study eating plan could benefit from consultation with a registered or licensed nutritionist to get them started.

[d]More than one drug may be required.

Figure 38-2 Typical presentation of axillary skin with acanthosis nigricans.

Although insulin stimulates glucose storage in muscle, it inhibits the glycogenesis and glycogenolysis in the liver (Figure 38-3).

In the MetS—or “insulin resistance syndrome”—the number of insulin

receptors is reduced. This downregulation is triggered by the existing hyperinsulinemia. Moreover, the tyrosine kinase activity of the insulin receptor is lowered, resulting in a further disturbance of the proximal signal transmission.

Insulin is an anabolic hormone and thus a negative regulator of the β-adrenergic-stimulated lipolysis.[9] With insulin resistance, there is a reduced insulin-mediated inhibition of basal lipolysis. Together with the increased body fat mass, this contributes to an increase in the level of circulating free fatty acids. They are in turn causally related to insulin resistance. For the development or strengthening of insulin resistance and reactive hyperinsulinemia, free fatty acids are responsible in three ways. They reduce the insulin binding to the receptor and decrease—depending on concentration—the intake of insulin and the degradation in the liver. A second mechanism is that the glucose utilization in the muscle is significantly impaired by the presence of high levels of free fatty acids. Free fatty acids inhibit the tyrosine phosphorylation of IRS-1. As a result, the activity of PI3-kinase is reduced and the transport of glucose is impaired. The resulting discrete hyperglycemia causes a stimulation of insulin secretion, with the consequence of hyperinsulinemia.

TABLE 38-5 Estimate of the Hereditability of Individual Components of MetS[8]

Phenotype	Estimated Hereditability (%)
Body composition	25–60
• BMI	25–40
• Body fat	40–55
• Abdominal obesity	
Insulin/glucose	10–75
• Fasting glucose	20–55
• Fasting insulin	46–90
• Insulin resistance or T2DM	
Lipids	25–60
• Triglycerides	25–60
• LDL-cholesterol	30–80
• HDL-cholesterol	50–60
• Total cholesterol	
Blood pressure	20–70
	10–50

• Systolic	50
• Diastolic	20–60
• Hypertension	30
• Hemostasis-related features	
• Microalbuminuria	

The third mechanism is shown in a stimulation of insulin secretion by the β-cell by high levels of free fatty acids.

The Role of Adipose Tissue in the Pathogenesis of Insulin Resistance and the MetS

The components of the MetS hypertension, dyslipidemia, and insulin resistance show a significant dependence on the manifestation of obesity and with that on the fat mass.

An analysis of 26,000 datasets of children and adolescents of the obesity patient registry (APV-registry) documented this in an impressive way (Figure 38-4). With increasing relative BMI, there is an increase in the values of the measured cardiovascular risk factors and the clustering of risk factors.

The described correlation between the measure of obesity and the manifestation of the individual components of the MetS implies a causal relationship between increased fat mass and metabolic changes. Recent studies have shown that the adipose tissue in particular the visceral fat mass contributes to the development of insulin resistance as well as to the development of dyslipidemia and the impaired β-cell function.[12] The increased levels of circulating fatty acids pass through the portal vein to the liver. They act as a substrate there for the endogenous synthesis of very-low-density lipoproteins, whose secretion is increased under these conditions.

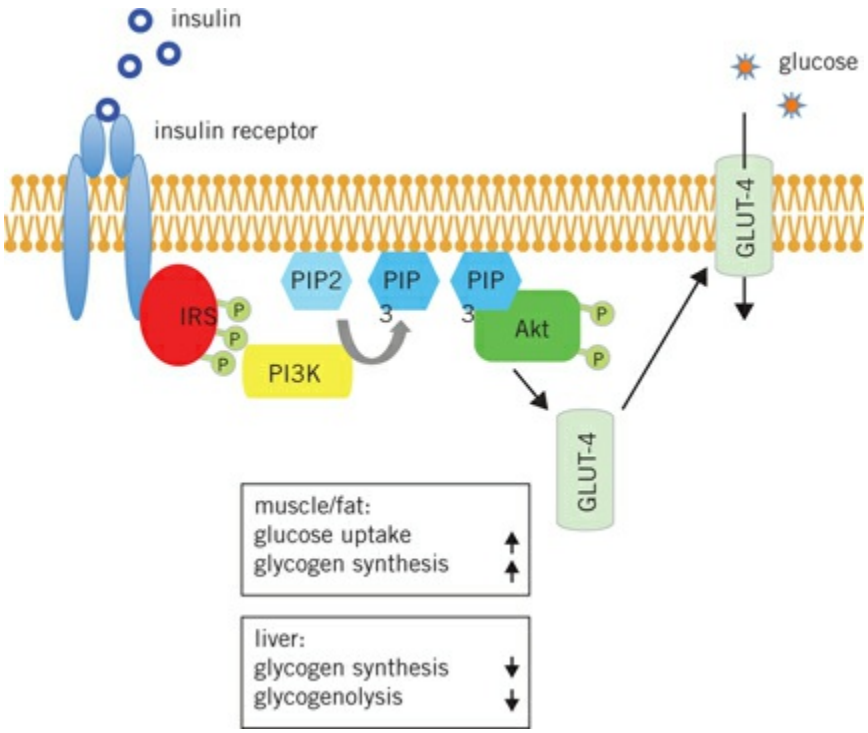

Figure 38-3 Insulin-mediated signal transmission (Wabitsch et al[10]). Insulin binds to the extracellular α-subunit of the insulin receptor. This leads to the autophosphorylation of the intracellular β-subunit of the receptor and the add-on phosphorylation of insulin receptor substrate proteins (IRS). This in turn results in the activation of phosphoinositide 3-kinase (PI3-K), which catalyzes the conversion of phosphatidylinositol diphosphate (PIP2) into phosphatidylinositol triphosphate (PIP3). The lipid molecule activates the key kinase Akt, which forwards the insulin signal now to the various cell effector systems. In adipose tissue as well as in muscle, the glucose transporter Glut-4 is translocated to the cell surface and glucose is added to the cell. Glycogen synthesis is stimulated, whereas hepatic gluconeogenesis and glycogenolysis are inhibited by insulin.

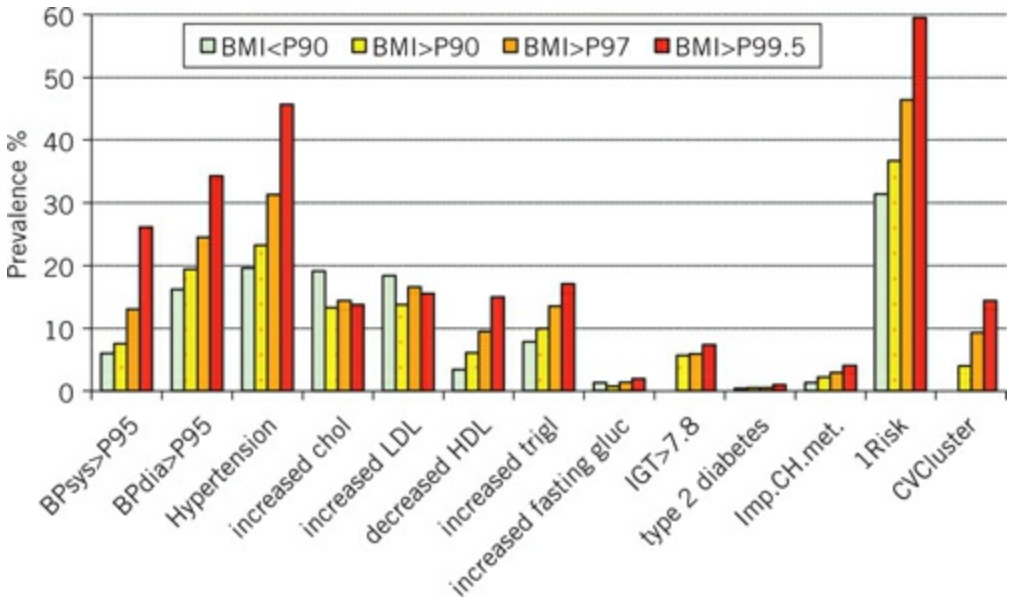

Figure 38-4 Cardiovascular risk factors in relation to BMI categories in 26,008 overweight children and adolescents—an analysis of the APV-registry.[11] Abbreviations: BP, blood pressure; BPdia, diastolic BP; BPsys, systolic BP; CH, carbohydrate; two or three cardiovascular (CV) cluster; accumulation of two or three or more than cardiovascular risk factors; Chol, cholesterol; DM2, diabetes mellitus type 2, impaired fasting glucose (IFG) >7 and/or 2 h OGTT >11.1 mmol/L; Fast.Glu, fasting glucose; HDL, high-density lipoprotein; IGT, impaired glucose tolerance >7.8 mmol/L after two hours of oral glucose-tolerance test (OGTT); Imp.CH.met, impaired CH metabolism; LDL, low-density lipoprotein; P, percentile; Trigl, triglyceride Modified from I'Allemand et al.[11]

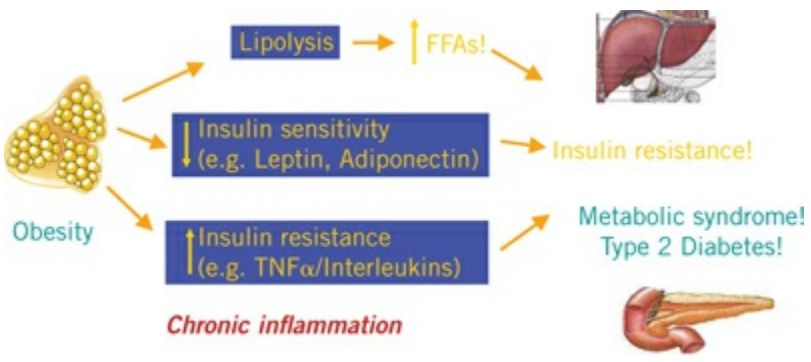

Figure 38-5 The role of adipose tissue in the pathogenesis of insulin

resistance and the metabolic syndrome.

The increased supply of glycerol and lactate in the portal circulation leads to increased gluconeogenesis and hepatic glucose production as a result of the substrate pressure.

Figure 38-5 shows the relationship between an increased fat mass and the development of insulin resistance, dysfunction of glucose regulation, and impaired β-cell function.

The adipose tissue produces many secretion products, which reduce insulin sensitivity and increase insulin resistance. Relatively large amounts of adipokines, which promote insulin resistance, are produced in visceral adipose tissue. In addition to the free fatty acids, these adipokines also result in the liver in an increased gluconeogenesis, in skeletal muscles to an impaired glucose absorption, and in pancreatic β-cells in an impaired insulin secretion.

A pathognomic feature of insulin resistance in obesity is known as **chronic inflammation** of the adipose tissue. This is characterized by the accumulation of macrophages that surround the adipocytes in a crown-like structure (Figure 38-6) and the expression of inflammation genes. These findings are observed very early in the adipose tissue, that is, before a significant increase in circulating insulin concentration. They also refer to an early pathophysiological event in the development of MetS.

ECTOPIC FAT STORAGE IN MUSCLE AND LIVER

Numerous experimental results support the idea that the adipose tissue may reach its capacity limits as the fat storage depot in obesity. In that case, the adipose tissue is characterized by hypertrophy of the adipocyte. These hypertrophic adipocytes are insulin resistant and produce typically high levels of insulin resistance–promoting adipokines. Interestingly, individuals with insulin resistance show ectopic fat accumulation in muscle and liver probably due to adipose tissue that has exceeded its capacity. Both by fat measurements on muscle biopsies and by modern methods of magnetic resonance spectroscopy, an increased ^{1}H-intramyocellular and intrahepatocellular triglyceride concentration was measured in patients with MetS. Increased muscle fat concentration is closely and inversely correlated with the insulin sensitivity of the body. The accumulation of intramyocellular fat is triggered by a reduced fat

oxidation in insulin resistance as well as by promoting the availability of fatty acids by increased lipolysis in adipose tissue. It has also been shown a direct link between visceral fat mass and the occurrence of nonalcoholic steatohepatitis, fat accumulation in hepatocytes. The findings of a fat accumulation in skeletal muscle and liver are typical findings in patients in which a MetS is present.

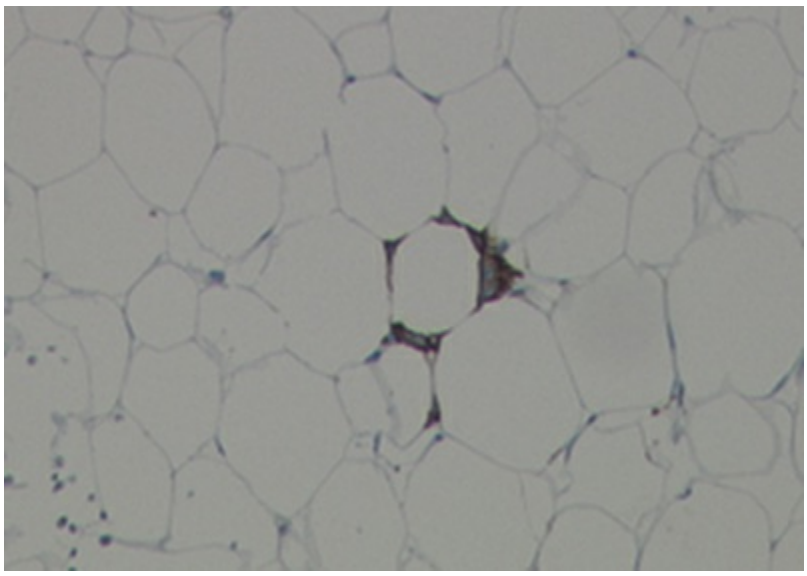

Figure 38-6 Obesity associated inflammation of adipose tissue. In obesity, increased macrophages migrate into the adipose tissue. In the figure, CD11c-positive macrophages are visible in visceral adipose tissue of an obese patient. Macrophages accumulate to a fat cell and form a crown-like structure. This inflammation of adipose tissue plays an important role for the pathogenesis of obesity-associated insulin resistance.

In this context, it is also interesting to see that patients without or with a lack of adipose tissue (e.g., with connatal or acquired lipodystophy), in which there also the maximum capacity of adipose tissue has been reached, have similar metabolic changes in the sense of MetS, as can be observed in obesity with insulin resistance. As in patients with obesity and MetS, in patients with lipodystrophies, there is also an accumulation of fat in the skeletal muscle and in the liver. According to that, a functionally healthy adipose tissue, which is characterized by a high insulin sensitivity and a high storage capacity, is essential for a healthy metabolism and helps to prevent the development of MetS.

PREVALENCE

In a study of 1205 obese children and adolescents aged between 4 and 16 years (965 of them were obese) Reinehr et al[13] could show that the prevalence of MetS differs significantly, depending upon which of the different published definitions were used. In the industrial nations, it can be assumed that the prevalence of MetS, depending on the definition of normal weight children is about 0.1%, of overweight children about 5%–8%, and of obese children about 20%–35%. According to a report by the International Obesity Task Force, cautious estimates indicate that about 20,000 young people in the European Union have an adult onset diabetes (mostly without knowing it); 400,000 have impaired glucose tolerance; 1 million adolescents show different indicators for cardiovascular diseases; and 1.4 million have a fatty liver disease (www.iaso.org/iotf/).

THERAPY

Although now there are good insights into the pathophysiology of insulin resistance and MetS available, there are still no causal therapies for MetS. Because of an insufficient number of longitudinal studies, which allow a reliable conclusion for the long-term prospective risk of MetS in childhood and adolescence, it is unclear whether MetS represents a distinct indication for treatment routinely. Undisputed, however, is the indication for therapy for components of MetS, hypertension, and impaired glucose tolerance, for which reliable risk evaluations exist.

In adolescents, it can be shown that the amount of daily physical activity is inversely associated with the occurrence of MetS. Furthermore, the prevalence of MetS in adolescents was lower, if the affected persons had a healthy diet including a lot of fruits.

Finally, it was convincingly shown that weight loss in children and adolescents leads to a significant improvement of the contributing factors of MetS.[14,15] These observations form the basis for today's behavioral treatment approaches, which primarily have the aim to enforce a change in the behavior of the affected persons. They have only limited effectiveness, however, and are generally not applicable for treating children and adolescents who do not find substantial support from their families and their social environment. Lack of compliance on the part of the affected persons and their families is often the essential problem.

If there is an indication of MetS in children and adolescents, intensive training with the aim to change the lifestyle, especially nutrition and

physical activity behavior, should be used alongside preventive measures (see below). By currently established obesity-training programs (e.g., Obeldicks, Babeluga, Freiburg Intervention Trial for Obese Children (FITOC), and others; see also www.a-g-a.de) these objectives can be achieved.

As an example for the effectiveness of simple behavioral changes, it should be mentioned that by the reduction of the daily fat intake and by the increase of fiber intake, a significant improvement of insulin resistance can be achieved. Increasing physical activity and muscle work is particularly significant.[16] Intensive training programs containing a physical activity program can lead—even after only two weeks—to a significant improvement in insulin sensitivity. This improvement is normally recognizable before a measurable weight loss. Physical activity increases glucose uptake in muscle, especially during intense physical activity. Muscle contractions during physical activity stimulate glucose transport additively to the effect of insulin. Physical activity improves the systematic effect of insulin with a lasting effect up to 72 hours. Physical training leads to an increase in cellular insulin receptors as well as to an increase in PI3-kinase activity. Physical training also reduces the systolic blood pressure, the muscular fat oxidation, and the LDL-cholesterol level.

If the components of MetS are insufficiently influenced by behavioral training and if there is an indication for therapy of associated diseases existing (hypertension, impaired glucose tolerance, dyslipidemia, see above), then drug treatment for these secondary diseases should be implemented.

PREVENTION

Prospective examinations suggest that effective behavioral preventive measures in primary prevention of MetS can be achieved through daycare centers and schools (involving parents). The measures should induce a change in nutrition and physical activity of children and their families. Thereby, a few specific behavioral changes are effective:

1. Reduction or waiver of intake of drinks containing sugar
2. Avoiding energy-dense snacks
3. Ensuring one to two shared meals at home per day
4. Controlled handling of fast food
5. Reduction of television and media time (screen time)
6. Increasing physical activity in everyday life

A consistent, negative relationship exists between the level of physical activity and manifestation of MetS. Interestingly, this relationship is independent of the degree of obesity and can be found to operate in the same way in lean and obese children. This finding indicates that adequate physical activity— *independent* of obesity—has a protective effect on cardiovascular risk factors.

The physical activity of children and adolescents has decreased in recent years. Increasing the time spent in physical activity is therefore an important target for prevention programs. It is still unclear how much physical activity a child needs to build optimal protection against MetS. It is recommended that children and adolescents integrate at least 60 minutes a day of moderate physical activity firmly into the daily plan.[7] The implementation of such projects in schools and daycare centers should have a high priority in addition to the dietary recommendations.

In view of the high and increasing prevalence rates for MetS, it is obvious that the causes of MetS can be found not only in individual behaviors of children and their families but also in the significantly changed living conditions in which today's children grow up. These have a strong and hardly controllable influence on dietary and physical activity behaviors. It follows that in the future, behavioral measures for the prevention of MetS, cardiovascular disease, and type 2 diabetes mellitus must be supported on various social and political levels (see also network causal factors http://www.a-g-a.de).

CONCLUSION FOR PRACTICAL EXPERIENCE

MetS is the pacemaker for the development of cardiovascular diseases and type 2 diabetes mellitus. The components of MetS should be evaluated in children with obesity. If there is evidence of the presence of MetS, special efforts should be made to decrease physical inactivity, to increase physical activity, and to avoid high-calorie and sugar-rich foods. With manifest hypertension or impaired glucose tolerance, early pharmacological treatment is necessary.

Childhood Obesity Prevention

39

John J. Reilly, BSc, PhD and Adrienne H. Hughes, BSc, PhD

CHILDHOOD OBESITY PREVALENCE AND TRENDS

In most high-income countries the prevalence of childhood obesity increased dramatically over the past few decades.[1] Recently, the rate of increase in the prevalence of childhood obesity appears to have slowed down in high-income countries,[2] but prevalence remains high and obesity rates have generally not slowed among children of lower socioeconomic status. Moreover, obesity prevalence estimates usually define obesity as a high body mass index (BMI) for age and sex, but such definitions are conservative, with a relatively high proportion of excessively fat children not identified as obese by BMI.[3] This means that most national estimates of childhood obesity prevalence underestimate the scale of the problem. Estimates of obesity prevalence based on the widely used "Cole-International Obesity Task Force" BMI-based definition of obesity are even more conservative.[3]

ARGUMENTS FOR EARLY PREVENTION OF CHILDHOOD OBESITY

There is now general agreement that childhood obesity prevention is important, and that attempts to prevent obesity should include the infancy–early childhood period. In brief, the arguments in favor of focusing obesity

prevention in early life are as follows. First, the obesity epidemic affected young children—they have not been immune from the societal changes that have affected the rest of the population. Second, there is a strong tendency for obesity to persist at any age, and it is more persistent when more severe[4,5]; many obese children will not simply "grow out of their obesity" without an intervention that helps them to do so. The longer term consequences of childhood obesity are generally more severe when obesity has its onset in early life.[5] There may also be critical periods in early life when children may be set on a path to later obesity, and even relatively short-term interventions in early life may therefore provide long-term protection against obesity. It is believed that obesity prevention in early life may be more effective than attempting to prevent obesity later in life, when obesity-promoting behaviors have become well-established. Finally, recent evidence suggests that attempting to prevent obesity in early life in the current generation of children may have beneficial effects on future generations of children via epigenetic mechanisms.[6]

ORIGINS OF CHILDHOOD OBESITY: ENERGY IMBALANCE

Obesity results from a chronic positive energy balance, a sustained excess of energy intake over the amount of energy expended. Although children need a small positive energy balance to grow (of less than about 50 kcal/d after the period of rapid growth in the first six months of infancy), the size of the energy imbalance in modern children who become obese is usually much larger.[7,8] Since energy imbalance depends only on the amount of energy being consumed and expended, the causes of obesity can seem very simple. This apparent simplicity can lead the public, health professionals, and health policymakers to the view that prevention or treatment of obesity should be simple tasks. In fact, it has become clear that children and their families live in a much more complex "ecology" and the "causes of the causes" of excessive energy intake or inadequate energy expenditure are very much more complex.[9] The UK government Foresight Report on tackling obesity,[9] for example, recognized over 200 factors that influence obesity, and these factors operate at different levels in an "ecological model": at the level of the child, the family, the local neighborhood, the school, national policy environment, and the international policy environment. In addition, the Foresight Report pointed out that many of these factors interact with each other in multiple and complex ways. In

summary, the apparent simplicity of the development of obesity disguises a marked complexity.

ESTABLISHED RISK FACTORS FOR CHILDHOOD OBESITY

Modifying the main risk factors for childhood obesity is the key to prevention. The complexity of childhood obesity has hindered our understanding of etiology, and other complexities arise from gaps in the evidence base on etiology, and from limitations arising from observational study designs. Most etiological studies to date have been observational, with the inherent limitations of observational studies, in particular difficulties in attributing cause and effect with certainty. High quality intervention studies which inform our understanding of etiology have been scarce.[8] A full understanding of the etiology and prevention of childhood obesity is therefore not available at present, but there is little doubt that obesity etiology is sufficiently well-understood to justify preventive interventions. Recent systematic reviews and meta-analyses of etiology have demonstrated that there is a fairly large body of fairly consistent and high-quality evidence.[10–14] Moreover, recent systematic reviews of preventive interventions have demonstrated a reasonably sizeable body of evidence upon which to design future research, clinical, or policy interventions, for example.[15]

Recent systematic reviews and meta-analyses of etiological studies have established a number of modifiable obesity risk factors in early life: rapid early growth, formula feeding, screen time, lack of sleep/disrupted sleep, low physical activity, and sugar-sweetened drinks. These risk factors promote an excessive energy intake, a reduced energy expenditure, or both, and are summarized in brief below.

Rapid Early Growth

Growing rapidly in utero, in infancy, or in early childhood strongly and consistently predicts increased risk of childhood obesity.[10–14,16] In the large Avon Longitudinal Study of Parents and Children (ALSPAC) cohort study in England, for example, the adjusted odds ratio (AOR) for obesity at age 7 years for those with catch-up growth (defined as gain in weight Z score of >0.67 from birth to 24 months[16]) was 2.6 compared to those with no catch-up growth.

One aspect of rapid early growth that promotes increased risk of

childhood obesity, but is not widely known, is early "adiposity rebound." The adiposity rebound (AR) is the period in childhood (typically between around age 3–6 years in western populations) when BMI begins to increase after reaching a nadir. In the ALSPAC cohort study, early AR (before age 3.5 years) was the risk factor that was most strongly associated with later obesity (AOR 15 vs. later AR after age 5 years), stronger even than both parents being obese (AOR 10 vs. neither parent obese).[16] Identifying the timing of AR in individual children is problematic because of the need to obtain a number of measures of BMI and plot them on a BMI for age reference chart, and so using the timing of rebound in clinical practice may be impractical. For public health applications, such as the planning of obesity prevention interventions, knowledge of the precise timing of AR is less important, and such applications simply need to focus on modifiable behaviors (discussed below) before the AR takes place.

The mechanisms that underlie the association between rapid early growth and later obesity are still not fully understood. Intervention studies that aim to reduce risk of obesity via modification of growth trajectory can be very informative of underlying mechanisms, and can provide potential clinical or public health strategies for preventing obesity.[17] For example, the recent European Childhood Obesity Trial suggests that modifying the protein content of infant formula may reduce the risk of developing "obesogenic" growth trajectories in early life.[17]

Formula Feeding

Formula feeding is a well-established risk factor for childhood obesity,[10,12] and this may be mediated in part by the impact of formula composition on growth trajectory, as suggested by the European Childhood Obesity Trial.[17] The concept that formula-feeding increases risk of childhood obesity remains controversial, but promotion of breast-feeding as a means of preventing obesity is relatively uncontroversial because it has so many other benefits.

Sedentary Behavior/Screen Time

High exposure to screen/media (particularly TV) is a well-established early risk factor for childhood obesity,[10,16] and many national and international guidelines on obesity prevention recommend that exposure to screens should be restricted in early life[18–21]: to less than 1 h/d for children aged 2–4 years and no more than 2 h/d for children aged 5 and over. Promotion of a reduction in screen time/TV viewing should have a number

of benefits for child health and development beyond obesity prevention and screen-time behavior seems to be modifiable, so this is a logical target of clinical or public health actions aimed at obesity prevention.

Lack of Sleep/Disrupted Sleep

Lack of sleep/disrupted sleep are increasingly well-established early risk factors for childhood obesity.[10,16] As with most of the well-established risk factors for childhood obesity, the mechanisms underlying the impact of sleep deficit on obesity risk are not fully understood. However, as with most of these risk factors, clinical or public health action aimed at promoting sleep should have a number of benefits for child health and development beyond obesity prevention, and sleep behavior seems modifiable, so this seems to be a justifiable target for obesity prevention efforts.

Low Physical Activity

Low physical activity predisposes children to increased risk of obesity,[10,22] and so is a justifiable target of clinical or public health efforts directed at obesity prevention. Low physical activity also increases the risk of a range of other health problems: physical activity is therefore worth promoting in its own right. National and international guidelines recommend accumulating at least 180 min/d of physical activity at any intensity for young children (aged 1–4 years) and 60 min/d of moderate to vigorous intensity physical activity for children aged 5 and over.

Sugar-Sweetened Drink Consumption

Consumption of sugar-sweetened drinks increases risk of childhood obesity,[1] and a number of other health problems, and appears to be modifiable,[23] so represents a logical target of clinical or public health efforts that aim to prevent childhood obesity.

Other Risk Factors for Childhood Obesity

A number of nonmodifiable risk factors (socioeconomic status, ethnicity, age, and gender) and less modifiable factors (notably parental obesity) have been associated with risk of childhood obesity in various studies. Although nonmodifiable or less-modifiable risk factors are of limited value in designing interventions, they can help identify families at high risk of obesity, as discussed below.

USING THE ESTABLISHED RISK FACTORS FOR CHILDHOOD OBESITY IN CLINICAL AND PUBLIC HEALTH PRACTICE

Planning Preventive Interventions

Having a substantial body of evidence on early life risk factors for childhood obesity provides health professionals and policymakers with a suite of "candidate" behavioral targets of obesity prevention interventions. The well-established candidates at present are rapid early growth, excess screen time, lack of sleep, low physical activity, formula feeding, sugar-sweetened drink consumption, as described above. Novel risk factors will emerge as new evidence comes to light.

There are so many well-established behavioral targets of obesity prevention interventions that it is helpful to prioritize them when planning research, clinical practice, or policy interventions. Logic frameworks should be helpful in prioritizing obesity prevention interventions. One of the earliest and most useful logic frameworks was that proposed by Whitaker,[24] who suggested that the highest priority clinical and public health preventive interventions for childhood obesity should meet the following criteria: there should be good evidence that the behavior or target is implicated in causing obesity, the behavior should be modifiable, modifying the behavior should do no harm, modifying the behavior should promote child health and/or development for reasons other than obesity. Applying these "Whitaker Criteria" should be useful to guide decisions on the behaviors to target in obesity prevention, and should "future-proof" such decisions, as the framework should be applicable when novel risk factors for obesity also emerge.

It is striking that the well-established early life behavioral risk factors for childhood obesity outlined above meet the "Whitaker criteria" well. A recent critique of research interventions, and clinical practice and policy interventions, to prevent obesity in the United Kingdom concluded that many such interventions do not meet the "Whitaker criteria" well.[25] In the UK preventive interventions are often not well-informed either by the evidence on etiology and interventions, or by the application of any logic model.[25]

The evidence summarized above has focused on *why* obesity develops during childhood. The issue of *when* obesity is most likely to develop during infancy, childhood, and adolescence, is important in the planning of population-based strategies for the prevention of childhood obesity, but

has been somewhat neglected. Many such interventions have failed to provide a rationale as to *when* (at what age) interventions should take place, for example, as highlighted in the review by Nichols and Swinburn.[26]

Preventive interventions in populations might be best targeted at stages of the life cycle when excess positive energy balance (or excess weight gain) is at its peak, when the incidence (development of new cases of obesity) is at its highest, and/or the stage at which obesity is least likely to resolve spontaneously. Cohort studies can be very informative of such issues. In the ALSPAC birth cohort in England, for example, one study attempted to identify at what point(s) in infancy, childhood, and adolescence excess weight gain was at its highest: this was in mid-late childhood (7–11 years).[27] A subsequent study in the ALSPAC cohort[28] also attempted to identify peak periods for the development of new cases of obesity, and again incident obesity was most likely during mid-late childhood (age 7–11 years). The generalizability of these ALSPAC findings is unclear, but obtaining similar evidence in other societies could be very helpful in making population-based obesity prevention more evidence-informed in future, and may increase the efficacy, effectiveness, and cost-effectiveness of future interventions.

Identifying Children and Families at High Risk of Developing Obesity

Knowledge of the suite of well-established risk factors for childhood obesity, and the magnitude of the risk which they provide, can permit health professionals to identify infants or children at high risk of obesity. This information could then be used to observe changes in growth more often as a result of a child being identified at high risk (e.g., by annual monitoring of weight and height in those deemed to be at high risk[29]), or to inform a decision to begin a weight management intervention. This sort of intervention could be based on an informal use of information on the presence or absence of obesity risk factors in each case, or could be more formal, for example, a screening tool for identifying those at high risk of obesity. The literature contains a number of formal screening tools that aim to quantify the risk of childhood obesity on the basis of the presence or absence of early life obesity risk factors. One recent research-based example is that from Morandi et al.[30] In England, an example of a clinical practice-based screening and management tool for early obesity prevention is provided by the "HENRY" program.[31] One basic question is whether or

not any such screening tools add value to the information which is both readily available in clinical practice and which strongly predicts risk of later obesity, that is, parental obesity.

Knowledge of the *magnitude* of the risk factors for childhood obesity is also likely to be helpful to health professionals and policymakers. Comparing the magnitude of increased risk associated with different obesity risk factors is problematic, but in the large ALSPAC cohort study in England[16] a number of risk factors were investigated within the same sample, and so the relative impact of the different risk factors can be assessed. Table 39-1 summarizes the AOR for each of the early life risk factors that were associated with obesity at age 7 years in the ALSPAC cohort study. It should be noted that if we are considering targeting preventive efforts at the population, rather than for the individual family, the population exposure will be important as well as the magnitude of the risk associated with each risk factor. Risk factors that are more prevalent in the population will usually have a greater impact on obesity than rare risk factors, even if they have only modest effects.

IMPLEMENTING INTERVENTIONS TO PREVENT CHILDHOOD OBESITY: EVIDENCE FOR OPTIMISM

The most recent Cochrane review on interventions for the prevention of childhood obesity in 2011[15] was very positive about the prospects for preventive interventions. It concluded that interventions that aimed to prevent childhood obesity should be successful so long as they implement changes in diet, physical activity, and sedentary behavior. The review even argued that most future research effort in childhood obesity prevention should focus on the question of *how* to implement such changes, as the question of whether such changes would be efficacious was now redundant.[15] This sort of evidence should help dispel pessimism about the prospects for obesity prevention interventions, and make it easier for health professionals and policymakers to argue for the development and implementation of interventions.

TABLE 39-1 Early Life Risk Factors for Obesity From the ALSPAC Study[16]

Risk Factor From Conception–Age 3	Magnitude of Obesity

Years	Risk at 7 Years
Rapid Growth • Very early AR (before age 3.5 y) • Every 100 g increase in birth weight • Every 100 g increase in weight from 0 to 12 m • Catch up growth (weight gain of >0.67 standard deviation scores in first two years)	AOR[a] 15 vs. later AR (after age 5) 5% increase in risk (AOR 1.05/100 g increase) 6% increase in risk (AOR 1.06/100 g increase) AOR 2.6 vs. no catch up
Parental obesity (both parents obese)	AOR 10.0 vs. neither parent obese
>8 h/wk of TV viewing at age 3	AOR 1.6 vs. < 4 h/wk
<10.5 h/night of sleep at age 3	AOR 1.5 vs. ≥ 12 h/night of sleep

[a]AOR, adjusted odds ratio.

TABLE 39-2 Promising Recent Early Life Obesity Prevention Trials

Age Group, Location	Trial/Intervention Name/Reference	Target of Intervention
Infants, Australia	Nourish[36]	Infant feeding
Antenatal–24 mo, Australia	Healthy Beginnings[37]	Infant feeding, active play
Infants, Europe	European Childhood Obesity Trial[17]	Growth modification via protein content of infant formula
2–5-y-olds, USA	Healthy Habits, Happy Homes[38]	Increased sleep, reduced TV, family meals
Birth–5 y, Australia	Infant[39]	Reduced sugar-sweetened drinks and TV, increased active play
	Romp and Chomp[40]	

A number of recent obesity prevention interventions, summarized in Table 39-2, have focused on modifying the well-established early life (infancy–early childhood) risk factors for childhood obesity discussed above, and they show great promise. These interventions may therefore be considered as a high priority for adoption in other settings, perhaps with modifications as appropriate to the circumstances. Alternatively, individual elements of these recent early life interventions might be generalizable to other settings.

GAPS IN THE EVIDENCE ON CHILDHOOD OBESITY PREVENTION

Although much evidence has accumulated on how to prevent childhood obesity, some notable gaps in the evidence remain. Recent systematic reviews have found very little evidence on preventive interventions outside the western world, in low-middle-income countries, for example, where the prevalence of childhood obesity is increasing markedly[15,32] and the capacity to deal with this increased prevalence is limited at present. The generalizability of much of the current research evidence on obesity prevention interventions to non-Western cultures in general, and to low-middle-income countries in particular, is unclear.

An additional notable gap in the evidence is on "upstream" interventions. In socioecological models of health the child is seen as being at the center- or base-of a complex hierarchy of influences on child health behavior and health outcomes. To date, systematic reviews on childhood obesity prevention have found evidence largely from studies that target the "micro-environment" of the child, family, and/or school, and there is much less evidence from interventions that target higher level influences in the hierarchy (e.g., changes in the national and international policy environment), despite the likely high degree of importance of such "upstream" influences.[33] Research that addresses the gaps in the evidence base on childhood obesity prevention should be an urgent priority.

One other gap in the evidence base that has been emerging as an important issue is the question of what are the main barriers to obesity prevention interventions in clinical practice and public health? Qualitative studies have been very informative in understanding the barriers to lifestyle change among groups who would be high priority targets of such interventions. For example, Lakshman et al[34] reported in a qualitative study of English mothers of infants that there was strong resistance to the types of preventive interventions that are indicated by the etiological evidence summarized above. Lakshman et al[34] found that their sample of mothers commonly and strongly believed that it was not possible to overfeed a baby, that infants crying always signaled hunger, that babies "can't be overfed," and that infancy was "too early" to intervene to prevent later obesity and related diseases, beliefs that are all at odds with the research evidence and the beliefs of most obesity prevention researchers. The possible need to overcome such barriers should be considered by those working in clinical practice. For those developing research-based preventive interventions, the most appropriate way to deal with barriers of this kind is to use a framework for the development of the intervention that takes specific account of them, and makes study participant beliefs central to intervention development, such as the UK Medical Research Council

Framework for the Development and Evaluation of Complex Interventions in Public Health.[35]

CONCLUSIONS

The evidence on the etiology of childhood obesity is incomplete, but more than sufficient to develop and implement evidence-informed obesity prevention interventions that target infancy and/or early childhood. Numerous modifiable and nonmodifiable early life risk factors for childhood obesity are now well established, and these have been summarized in this chapter. Interventions that target the modifiable risk factors would generally do no harm and would also improve child health and development in many other respects, beyond obesity. A number of promising "model" interventions exist and these should be considered as priorities for translation beyond their original research settings and populations.

The well-established early life risk factors for childhood obesity should be the basis of future evidence-informed preventive efforts in research, clinical practice, and health policy, and used for identifying families and population groups at particularly high obesity risk. As novel obesity risk factors come to light these should be prioritized for action if they are based on good evidence of causality, and if their modification is likely to do no harm and benefit child health and development in other ways.

The Nutrition Transition and Global Child Health

40

Benjamin Caballero, MD, PhD

Health professionals in today's world must keep current on the global health situation, since some of the major domestic health issues, such as HIV/AIDS and obesity cannot be addressed without a global framework. Furthermore, the dramatic expansion of global trade, travel, and communications have torn physical and cultural barriers, exposing most of the world's population not only to communicable diseases but also to dietary and lifestyle practices carrying common risk factors for chronic disease. In this chapter we present an update of current trends on these risk factors, and discuss their impact on children and on the general population.

The world population reached its seven billion mark sometime in October 2011. As expected, the continuing reduction in child mortality over the past several decades led to declining fertility, and by the end of the 20th century all but 16 countries had experienced this demographic transition.[1] This relative slowing in population growth over the past 30 years is one of the important elements of the global nutrition transition. The other, discussed below, is that the vast majority of predicted growth in world population will take place in urban environments of developing countries.

GLOBAL TRENDS IN DISEASE BURDEN

Global disease burden continues its transition from communicable diseases

and predominance of children's diseases to chronic, noncommunicable diseases affecting primarily adults.[2] This epidemiological transition is driven by a combination of reduction in childhood mortality, ageing of the world population, and emergence of chronic noncommunicable diseases of the adult, such as obesity, diabetes, and cardiovascular diseases.[3] These trends are documented in the most recent Global Burden of Disease Study,[4] which compared changes in disability-adjusted life years (DALYs, a metric that reflects the number of life years lost to premature death or disability) between 1990 and 2010. For children under 5 years, overall DALYs declined from 41% in 1990 to 25% in 2010. Over the same period, the DALYs attributed to diarrheal diseases, one of the most common causes of illness in children, decreased by 51%. Conversely, the leading cause of DALYs worldwide was ischemic heart disease, a typical disease of the adult. These shifts are also reflected in the changing composition of DALYs, with a reduction in the contribution of premature mortality (dominated by infant and childhood mortality) and an increase in disability years (driven by chronic diseases of the adult).

In another report, the Global Burden study expanded the analysis of DALYs to assess attributable risk factors for leading disease burdens.[3] From this analysis, the most evident shift among the leading 10 risk factors is childhood underweight, which moved from first place in 1990 to eighth place in 2010. Conversely, high body mass index, which was not in the top 10 in 1990, became the sixth leading risk factor in 2010. Risk factors affecting primarily children, such as water sanitation and micronutrient deficiencies, also declined during that period. A comparison of the top 10 risk factors for global disease burden in 1990 and 2010 is shown in Table 40-1.

TABLE 40-1 Top 10 Causes of Global Disease Burden in 1990 and in 2010, Both Sexes

	1990	2010
1	Childhood underweight	High blood pressure
2	Household air pollution from solid fuels	Tobacco smoking
3	Tobacco smoking	Alcohol use
4	High blood pressure	Household air pollution from solid fuels
5	Suboptimal breast feeding	Diet low in fruits
6	Alcohol use	High body-mass index
7	Diet low in fruits	High blood glucose

8	Ambient particulate matter pollution	Childhood underweight
9	High blood glucose	Ambient particulate matter pollution
10	Iron deficiency	Physical inactivity and low physical activity

Data are number of deaths per 1000 live births.

Source: Adapted from Hill et al.[8]

Behind these global trends are dramatic regional differences in disease burden and risk factors. In sub-Saharan Africa, childhood diseases and mortality are still predominant public health problems, and communicable diseases continue to be major contributors to DALYs.[4] Similarly, leading risk factors in that region are childhood underweight, household air pollution, and inadequate breast-feeding.[3]

GLOBAL TRENDS IN CHILD MORTALITY

Childhood deaths are the end-result of the complex interaction between health, nutritional and environmental factors. In the developing world,

underweight, micronutrient deficiencies (vitamin A, zinc, iron), and suboptimal breast-feeding lead to aggravated morbidity and higher risk of death from diseases such as pneumonia, diarrhea, measles, HIV/AIDS, and malaria.[5] A contaminated environment (unsafe sanitation, air pollution) is also a common contributor. Other determinants include access and utilization of prenatal care, immunizations, and maternal education.[6]

Global rates of under-five child mortality (U5MR) have been declining modestly but consistently for the past two decades, albeit at a pace too low to meet the targets defined by the Millennium Development Goals (MDG).[7] Still, an important milestone was reached by 2010, when for the first time the number of under-five deaths fell below the 10 million/year mark. A revised methodology for mortality estimates was recently introduced by UN agencies.[8] Using this new approach, the data show that between 1990 and 2010 U5MR has declined from 88 to 57 per 1000 live births, equivalent to a reduction from 12 million deaths in 1990 to 7.6 million in 2010.[8] During these 20 years, the rate of decline in mortality has slightly accelerated from the first decade to the second (1.9%–2.5%), but remains well below the MDG target of 4.4% per year. Infant mortality rate (deaths in the first 12 months of life), which accounts for almost 40% of U5MR, has also declined, from 32.5/1000 in 1990 to 22.8/1000 in 2010.[8] There is a marked difference in mortality rates between developed and developing countries. For U5MR, the 2010 figures are 6.8/1000 for developed countries and 62.7/1000 for developing countries. Similarly, there are clear disparities in mortality rate within the developing world, as shown on Table 40-2.

Major factors driving the continuing reduction in child mortality are improved sanitation, expanded immunization and micronutrient supplementation programs, and breast-feeding promotion. Maternal education and income, and social empowerment of women of reproductive age have also been found to favorably impact on child mortality. The continuing reduction in child mortality usually leads to a reduction in population fertility, which in turn favors child survival.[1]

UNDERNUTRITION

Undernutrition in all its forms, including fetal growth restriction, are major factors determining mortality risk in children under 5 years of age, and are responsible for 2.2 million deaths of children under 5 years of age every year.[5] Childhood underweight continues to decline globally, but with

important disparities across countries and regions. Global geographic distribution of under- and overweight in children is presented in Figures 40-1A and B.

The most common definition of undernutrition is low body weight for age, based on reference standards such those of the WHO.[9] Chronic undernutrition or *stunting* defines a deficit in longitudinal growth, and is assessed by height-for-age. *Wasting* is usually an acute or subacute form of undernutrition, in which there is a loss of body mass relative to height that occurs in a relatively short time, and is diagnosed using weight-for-height. Each of these conditions can be defined as moderate or severe, based on the degree of deficit of the corresponding indicator. Data from UNICEF/WHO/World Bank for children under 5 years[10] show that stunting has declined globally from 32.5% in 1990 to 25.7% in 2011, and is projected to fall further to 22% by 2025. By 2011, the prevalence rates in developed and developing regions were 7.2% and 28%, respectively. Since the pace of decline is substantially faster in developing countries, it is expected that this gap will continue to decrease, as has been the case for the past two decades. East Africa (42.1%) and Oceania (35.5%) are the regions with the highest stunting prevalence.[10]

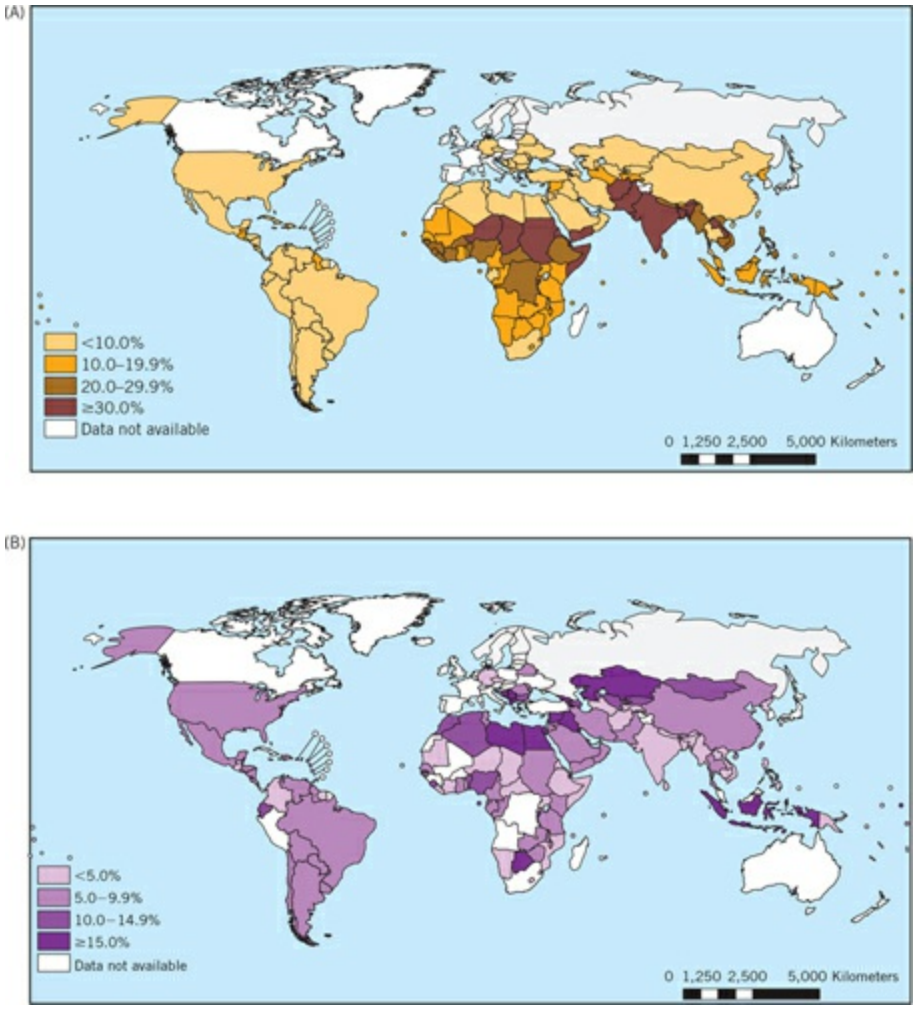

Figure 40-1 A, Global distribution of under-five prevalence of underweight (below –2 SD of the median weight-for-age). Reproduced from UNICEF-WHO-World Bank.[10] B, Global distribution of under-five prevalence of overweight (above +2 SD of the median weight-for-height). Reproduced from UNICEF-WHO-World Bank.[10]

Several studies have demonstrated an inverse correlation between stunting and cognitive and physical development.[11] Childhood stunting also leads to reduced physical work capacity in the adult[12] and has an important transgenerational effect that perpetuates the cycle of suboptimal growth and reduced productivity in a population.[13]

Wasting can occur in a previously healthy child, but most commonly occurs in children who are already stunted or that have experienced previous acute episodes of growth faltering. Acute weight loss may be caused by inadequate dietary intake due to illness or simply to

unavailability of food. A rapid drop in food availability can be caused by natural or human-made disasters, including war and forced population displacements. Wasting is less common than stunting, and while it has experienced modest but consistent declines over the past two decades, it still affects 8% of children worldwide, which represents almost 50 million children (Table 40-3), essentially all of them residing in the developing world.[14]

FETAL AND EARLY POSTNATAL GROWTH

Birth weight is a commonly used indicator of fetal growth, particularly during the last trimester of pregnancy. Low-birth-weight (LBW) infants have a 10-fold higher risk of neonatal mortality compared with newborns weighing 3–3.5 kg.[15] The prevalence of LBW in the developing world ranges from 8% in Latin America to 27% in South Asia,[14] and is on a gradual downward trend. Although prematurity is the main contributor to LBW in the developed world, the vast majority of LBW infants in developing countries are small for gestational age, reflecting intrauterine growth retardation (IUGR). The more common type of IUGR in the developing world is symmetric IUGR, indicating a sustained energy restriction throughout pregnancy.

Maternal prepregnancy weight is strongly correlated with birth weight. A low prepregnancy body mass index is associated with higher morbidity and mortality for both mother and fetus.[16] Thus, there is an intergenerational effect of stunting, because stunted girls reaching their reproductive age will have an increased risk of producing LBW babies.[13] Maternal behaviors and cultural factors determining level of physical activity and food intake also influence energy balance during pregnancy.

TABLE 40-3 Estimated Regional and Global Prevalence (%) of Undernutrition in Children Under 5 Years of Age, 2011

Region	Underweight[1]	Stunted[2]	Wasted[3]
AFRICA	17.7	35.6	8.5
Eastern	19.3	42.1	6.7
Middle	17.4	35.0	9.3
Northern	6.5	21.3	8.2
Southern	11.9	30.8	5.7

Western	21.8	36.4	10.4
ASIA	19.3	26.8	10.1
Eastern	3.1	8.5	2.3
South-Central	29.8	36.4	14.8
South-Eastern	16.6	27.4	9.7
Western	4.8	18.0	3.5
LATIN AMERICA & CARIBBEAN	3.4	13.4	1.4
Caribbean	3.5	6.7	3.4
Central America	3.9	18.6	1.0

OCEANIA	14.0	35.5	4.3
Developing countries	17.4	28.0	8.8
Developed countries	2.4	7.2	1.7
World	15.7	25.8	8.0

[1] Moderate or severe underweight: below -2 standard deviations (SD) of the median for weight-for-age of the WHO reference.

[2] Moderate or severe stunting: below -2 SD of the median for height-for-age of the WHO reference.

[3] Moderate or severe wasting: below -2 SD of the median for weight-for-height of the WHO reference.

Data does not include Japan, Australia, or New Zealand.

Source: Adapted from UNCEF-WHO-World Bank.[10]

Micronutrient deficiencies can also affect fetal growth, as well as impact on obstetric mortality. Vitamin A deficiency appears to have a significant effect on maternal mortality, as suggested by studies in Nepal where vitamin A supplementation reduced mortality by 30%.[17] Other studies in Nepal reported that prenatal folic acid and iron supplementation had also a modest positive effect on birth weight.[18] Data are less clear on the effect of zinc on birth weight, although studies in Peru found significant effects of prenatal zinc supplementation on fetal neurobehavioral development.[19] Additional maternal factors increasing the risk of LBW are low maternal age (<18 years), chronic infections, such as malaria, gastrointestinal parasites, sexually transmitted diseases (STDs), and first-time births.[15]

IUGR has long-term effects beyond birth weight. Studies in the developing world have reported lower Bayley scores and lower mental development index scores in LBW infants.[20] These findings are associated with environmental factors as well, such as standard of living, housing, and parental education. The trends in these studies would suggest that

cognitive development and deficits change over time, and many of the conclusions drawn are dependent at the age at which they are actually followed up, and may actually be transient.[21]

Under the appropriate conditions, LBW infants may be able to recover their weight through "catch-up" growth during the first few years of life. The Guatemala longitudinal study[22] documented some degree of catch-up growth of infants with IUGR during the first two years of life, with subsequent stabilization at the centiles achieved by that age. Nevertheless, body weight and height deficits in 17- to 19-year-olds were evident, averaging 5 kg and 5 cm below non-IUGR children.[23]

In the postnatal period, growth performance during the first 12 months of life appears to be critical for conditioning long-term body size and vulnerability to disease. Data from Latin America, sub-Saharan Africa, and South Asia (Figure 40-2) show the dramatic decline in height-for-age over the first 12 months of life, resulting in a sustained deficit (stunting) over the following years.[24] This evidence underscores the need for early intervention to prevent growth faltering. This window of opportunity to prevent stunting is commonly known as "the 1000 days."

FETAL AND EARLY POSTNATAL GROWTH AND RISK OF ADULT DISEASE

The "Barker hypothesis" originated from Barker's observation of an association between LBW and adult cardiovascular disease.[25] These original observations evolved into an important field of research, known as the developmental origins of health and disease. Its aim is to define the role of fetal and early postnatal growth patterns on long-term susceptibility to chronic, noncommunicable chronic diseases. There is now a consistent body of evidence, including cohort studies and mechanistic experiments, documenting the impact of early growth and metabolic differentiation on long-term risk of disease. Chapter 27, Human Growth and Disease Later in Life, provides further discussion of this concept. A compelling evidence emerged from cohort studies of the Dutch famine in World War II, showing increased adiposity in adults born to mothers who experienced energy restriction during gestation.[26,27] Similarly, cohort studies in India[28] and Guatemala[29] found associations between birth weight or early postnatal growth retardation and increased adiposity, blood pressure, or insulin resistance later in life. Taken together these observations suggest that the increased risk stems from periods of accelerated growth, such as

catch-up growth, perhaps when it occurs at critical times of maturation. This interpretation has raised concern on the potential long-term adverse consequences of rehabilitation of malnourished children, which usually involve at some point high rates of growth. Some studies in nutritionally rehabilitated LBW infants have shown significantly higher rates of excess adiposity, insulin resistance, and elevated blood pressure at 3–5 years of age.[28,30,31]

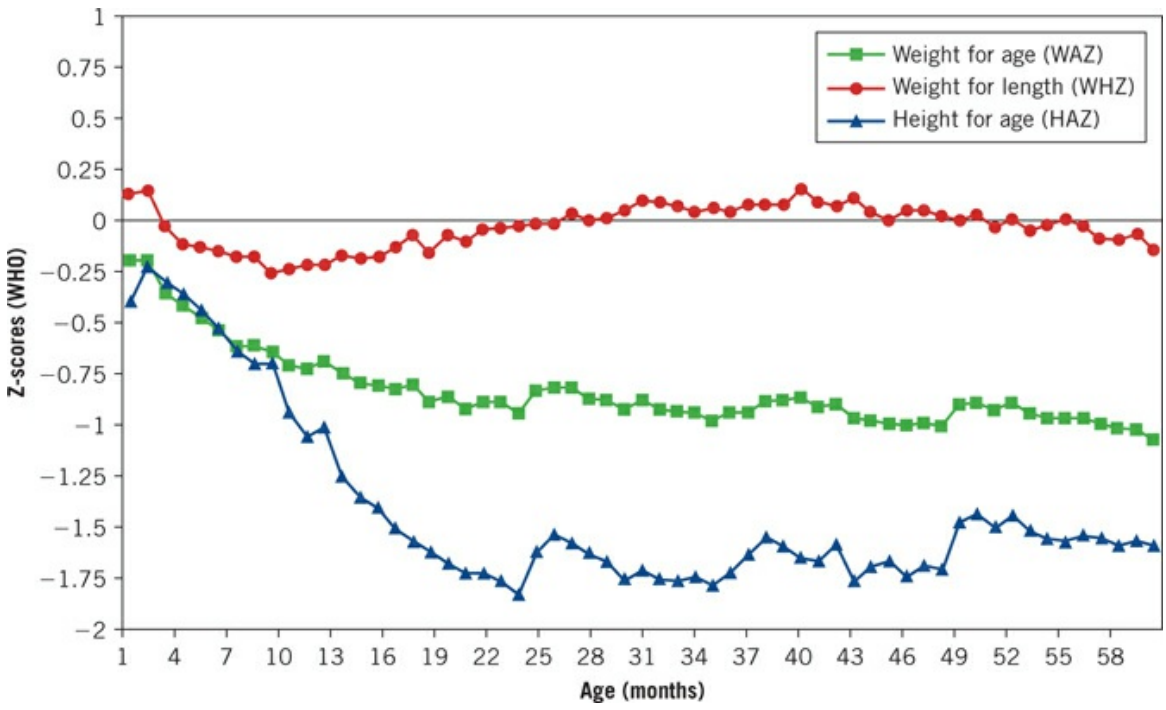

Figure 40-2 Mean anthropometric z-scores for age, relative to the WHO growth reference standard. Data from 54 countries in the WHO Global Database on Child Growth and Malnutrition. Reproduced from Victora et al.[24]

Beyond the potential risks associated with growth restriction and recovery, neonatal illness in general carries a heavy lifelong burden in developing countries. A study in Bangladesh estimated that neonatal conditions accounts for 195 years lost to disability for each 1000 neonates.[32]

UNDERNUTRITION AND SUSCEPTIBILITY TO

COMMUNICABLE DISEASES

The vicious circle of protein-energy malnutrition, impaired immune response, increased infections, and decreased food intake are well recognized since the seminal work of Scrimshaw et al.[33] In spite of the global epidemiological transition toward chronic, noncommunicable diseases, infectious diseases continue to be important disease burdens for children in developing countries. For example, a recent analysis of data from 84 countries estimated that diarrheal disease was responsible for 30% of deaths in children <5 years of age.[34]

Malnutrition affects most of the host defense systems against infection, including epithelial and mucosal integrity, mucociliary clearance, gastric acid production, immunoglobulin synthesis, and lymphocyte differentiation.[35] Micronutrient deficiencies, particularly of vitamin A and zinc, also result in severe impairment of host resistance mechanisms. The role of vitamin A on the immune system and on infectious disease morbidity and mortality has been extensively studied.[36–38] Evidence from field trials led to the policy of routinely administering high dose vitamin A supplements to children at risk of hypovitaminosis A. The role of zinc deficiency on susceptibility to infection and the efficacy of supplementation to reduce infection morbidity and mortality were also explored in several field trials, which showed that zinc supplementation significantly reduces the incidence of pneumonia and diarrhea, with a modest but significant effect on mortality as well.[39,40] See also Chapter 14 (Protein Energy Malnutrition).

Repeated, nonlife threatening infectious episodes can have a devastating effect on growth during the first years of life. The landmark work of L. Mata in the village of Santa María Cauqué in Guatemala[41] documented the slow but progressive growth delay during the first year of life in children suffering from minor but frequent episodes of acute infections, such as gastroenteritis, urinary tract infection, and upper respiratory infection. These episodes result in decreased dietary intake because of anorexia or withholding of food by caregivers, excess nutrient losses, and increased nutrient requirements.[42] In addition, the immune response to infection induces a catabolic state that may persist beyond the clinical course of the infectious episode, as shown by the pioneering studies of Beisel.[43]

MICRONUTRIENT MALNUTRITION

Single- and multiple-nutrient deficiencies are widespread, affecting over two billion persons worldwide, mostly but not only in developing countries. Iron deficiency is considered the most prevalent single-nutrient deficiency, affecting over one billion persons, and is perhaps the only micronutrient deficiency that has public health significance for developed countries as well. See Chapter 9 (Iron). We will only point out that about 40% of children in developing countries are anemic, largely because of iron deficiency.[44] Although marginal iron intake is a common factor, many times anemia is triggered by acute infectious diseases that may increase losses or reduce food intake.

Other major micronutrient deficiencies are hypovitaminosis A and iodine deficiency.[16] Although data on zinc deficiency is more limited, extensive regions with moderate or high risk for deficiency have been identified as well.[5] Along with inadequate dietary intake, infectious diseases are an important contributor to micronutrient deficiencies. They increase gastrointestinal losses and may impair effective utilization of dietary sources as well. Conversely, micronutrient deficiencies may increase susceptibility to infection, as noted above.

Vitamin A deficiency is one of the major single-nutrient deficiencies in the world. The WHO estimates that currently there are over 250 million children <5 years of age who are vitamin A deficient, and up to half-million of them will become blind every year.[44] In addition, vitamin A deficiency increases the risk of maternal mortality and may cause night blindness during pregnancy.[17,45] Among the main factors contributing to this deficiency are low consumption of animal protein sources, reduced bioavailability and bioconversion of dietary provitamin A (beta-carotene), and excess losses during episodes of acute infection.

Traditionally linked to blindness, the role of vitamin A deficiency on child mortality was demonstrated by the landmark studies of Sommer et al in the early 1980s,[46] showing that children who exhibited mild xerophthalmia had significantly higher mortality that those without signs of vitamin A deficiency. He subsequently showed that a single large dose of vitamin A resulted in a 30% reduction in child mortality.[47] Numerous subsequent trials in different countries have confirmed those findings, yielding on average a reduction of about 20% in mortality.[48] Supplementation is now a national policy in most countries with endemic hypovitaminosis A. The effect of vitamin A on mortality is likely due to its positive effects on integrity of epithelia, cell differentiation, and the immune system, thus reducing the severity of many infectious diseases,

particularly gastrointestinal and respiratory.[49,50]

Zinc deficiency is an emerging concern in the developing world, although there are less survey data than for other micronutrients, in part because of the difficulty in defining a standardized, reliable biomarker of zinc status in children. At-risk populations may be identified by assessing their dietary intake, alone or combined with other biochemical indices of zinc status. A geographic distribution of zinc deficiency was reported by Black et al.[5] Zinc supplementation trials have shown that it reduces the incidence of acute lower respiratory infections,[51] limits the severity of severe pneumonia,[39] and reduces the morbidity and mortality because of diarrhea.[52] Although most trials have administered the zinc supplement daily, weekly dosing appears to be also effective, assuming adequate compliance.[40]

Iodine deficiency continues to be the most common nutritional cause of brain damage worldwide. Fortunately, salt iodization has progressively reduced the incidence and prevalence of iodine-deficiency–related disorders, including cognitive and mental impairment, growth failure, and cretinism.[44] Although the number of countries where iodine deficiency is a public health problem has dropped by half over the past decades, the WHO estimates that there are still 54 countries with iodine deficiency in part or all of their territory. But it is the hope that with continuing efforts to promote and sustain iodine fortification, iodine deficiency may be confined to a few remote regions in selected countries.

Multiple-nutrient deficiencies are receiving increasing attention, particularly during reproductive age. The role of folic acid on pregnancy is well recognized in developed countries, but evidence reflects conditions that differ from those of developing country populations, who are likely to present folic acid deficiency combined with other micronutrient deficiencies. Field trials evaluating the impact of prenatal supplementation with multiple micronutrients on infant mortality[17] and birth weight[18] have yielded inconclusive results. Long-term follow-up (up to age 7 years) of offsprings, however, showed that the combination of folic acid–iron supplementation during pregnancy reduced mortality by 31% between birth and 7 years of age.[53] Similarly, other field trial demonstrated that antenatal supplementation with a combination of iron, folic acid, and zinc improved linear growth in schoolchildren.[54]

COMBATING MICRONUTRIENT MALNUTRITION

Based on the evidence from numerous field trials showing significant benefits from micronutrient supplementation, several countries have implemented regional or national supplement distribution programs. Although the supplement themselves are usually inexpensive, the logistics of mass distribution (transportation, coverage, etc.) are complex and difficult to sustain over time. Distribution programs, therefore, are considered an interim response to endemic deficiencies, with the ultimate goal of ensuring adequate intake through locally available foods, with or without fortification. Nevertheless, given the complexity of factors affecting food availability and intake in different populations, it is likely that micronutrient supplementation will continue to be a cost-effective option for the immediate future. See Chapter 45 (Interventions in Global Child Health) for more discussion on this topic.

Food fortification is a powerful approach to combat micronutrient malnutrition. Although its implementation and sustainability is more complex than for supplement distribution, it can take advantage of the market forces and food distribution channels, requiring little direct involvement from the target population. The requirements for a successful fortification program have been well defined.[55] A number of countries have implemented fortification programs with varied degree of success. Similarly, folic acid fortification had a significant impact on the prevalence of neural tube defects. Agricultural policies can provide incentive to rotate crops and to enhance the diversity and yield of foods grown and available. Agricultural technology, selective crop breeding, and transfer of technology may aid in increasing the micronutrient content of particular foods. Subsidization of certain seed types and of fertilizers may aid in encouraging the horticulture of certain crops as well. Finally, sustainability will ultimately depend on progress in educating consumers and on the overall behavioral change of the population.

THE NUTRITION TRANSITION

The dramatic advances in communications and transportation and the globalization of economic markets have resulted in rapid changes in diet and lifestyle in developing countries. This phenomenon, often called the nutrition transition, is a key factor in the changing disease patterns for developing countries.[56,57] Other factors are the increase in number and the aging of the world population. In turn, these changes led to a preeminent role of chronic, noncommunicable diseases as global cause of death, which by 2010 accounted for two of every three deaths worldwide.[2] The majority

of these deaths occur in low- and middle-income countries.

One of the critical consequences of the nutrition transition is the continuing rise on childhood obesity prevalence. It is estimated that there are over 42 million children <5 years of age who are overweight or obese (Table 40-4), more than 80% of them residing in the developing world.[58] By 2010, obesity prevalence in children <5 years reached 6.7%, up from 4.2 in 1990, and is expected to continue to increase in the coming years.[10] A more detailed discussion of this topic is available elsewhere,[59] and in Chapters 37, 38, 39, 40, and 47.

The three major factors driving the nutrition transition are food type and availability, urbanization, and lifestyle changes leading to reduced physical activity and increased sedentary time. Dietary changes are dominated by an overall increase in energy availability (except in sub-Saharan Africa), mostly because of higher consumption of vegetable oils and refined sugars, with modest reductions in cereals and pulses.[60] A particular phenomenon is the global increase in consumption of caloric sweeteners, primarily in beverages.[61,62] Although much debate on the role of energy-dense, low-nutrient foods (sometimes called “fast” or “junk” foods) have centered in the United States, over half the revenues of United States fast-food companies come from overseas markets, driven by their rapid growth in low- and middle-income countries.[63]

Urbanization, which occurs at a faster pace in the developing world, is having a profound effect on dietary patterns and lifestyle. The UN predicts that almost 90% of the projected population growth for the next 20 years will occur in urban areas of the developing world.[64] The urban environment has important effects on dietary and lifestyle patterns. Consumption of processed foods, usually of higher fat content, and total dietary energy intake tends to increase.[56] Even the modest improvement in income that may be associated with urban migration may initially have a detrimental effect on diet quality, by providing access to processed, energy-dense foods, as is suggested by data from Brazil[65] and China.[66] Urban families become dependent on the cash food market, which exhibit high price elasticity, thus having the potential for driving food choices in low-income populations.

TABLE 40-4 Estimated Regional and Global Prevalence (%) of Overweight in Children Under 5 Years of Age in 1990 and 2011

Region	1990	2011
AFRICA	4.2	7.3
Eastern	4.4	5.0
Middle	3.5	5.8
Northern	7.3	13.1
Southern	6.1	16.3
Western	1.9	6.6
ASIA	3.7	4.7
Eastern	6.8	5.5
South-Central	2.0	3.1

Developing countries	4.1	5.7
Developed countries	7.4	14.5
World	4.5	6.6

Overweight: above +2 SD of the median weight-for-height of the WHO reference.

Source: Adapted from UNICEF.[14]

Daily energy expenditure in the urban setting is usually substantially lower than in rural areas. The intense physical labor of rural work in the fields is replaced by sedentary, low-energy work.[67,68] Television viewing is also a well-documented factor in increasing physical inactivity in children,[69] and can also negatively affect consumption of healthy foods.[70] An increased energy intake and a reduced energy output lead to excess weight gain and obesity.

THE NUTRITION TRANSITION, POVERTY, AND CHILD HEALTH

The nutrition transition, particularly urbanization, has an important impact on child health. Over one billion children already reside in urban areas, and this figure will continue to increase in the foreseeable future.[14] While

urban dwelling may bring some benefits, such as better sanitation, access to health services, and job opportunities, at the same time it frequently magnifies social and economic disparities between rich and poor. Unemployment, insecure housing, street violence, and social isolation draw a sharper contrast between those who benefit from urbanization and those who are negatively affected by it. Indeed, some health indicators of child health show a significantly larger gap between rich and poor in urban than in rural areas.[71,72] Furthermore, some of the potential benefits, such as sanitation, are not keeping up with population growth in urban areas, and may remain a privilege for the few.[14]

The health effects (specifically on obesity prevalence) of socioeconomic development are the result of multiple factors, and are by no means linear. Low- and middle-income countries show different associations between gross domestic product and obesity prevalence.[73] An analysis by Jones-Smith et al[74] showed that the differential effects of increases in GDP on obesity rates may be mediated by differences in income inequalities within country.

Although the epicenter of the global crisis of 2007–2008 was in the developed economies, it has caused a worldwide recession affecting virtually every country. According to the International Labor Organization, in 2012 there were 25 million more unemployed than in 2007, with rates twice as high in the younger population.[75] The potential effect of these changes on health outcomes is still not clear, but major economic readjustments under way in many LMIC may result in further constraints in basic health care services for the poor.

CONFRONTING THE EFFECTS OF THE NUTRITION TRANSITION

There is compelling evidence of the impact that socioeconomic development and the nutrition transition are having on global health. A handful of modifiable risk factors, including tobacco and alcohol use, low consumption of fruits and vegetables, and physical inactivity, are having a disproportionate impact on disease burden. The WHO and other organizations have developed a global framework to combat these risk factors, endorsed by all UN countries.[76,77] Along with the MDG,[7] they provide a consistent action plan. Indeed, a number of countries have made significant progress toward the MDG, and practical experiences on preventing obesity in children have been disseminated.[78] But the MDG do

not address directly the problem of chronic, noncommunicable diseases. To confront these, the environment favoring obesity, predominant today in many countries, need to be changed. Policy decisions are necessary to increase the availability and affordability of healthy foods, limit access and promotion of unhealthy foods to children, create opportunities for safe recreational physical activity and reduce sedentary time at home and school. Some countries that are at an advanced stage of the nutrition transition, such as Brazil and Mexico, have begun to implement some of these policies, and can offer a template for others to follow.

Infant and Young Child Feeding in Low- and Middle-Income Countries

41

Souheila Abbeddou, MSc, PhD and Kenneth H. Brown, MD

INTRODUCTION

Breast-feeding and complementary feeding are key contributors to children's nutrition and health during the first two years of life.[1] In this chapter, we provide an overview of (1) current recommendations regarding optimal breast-feeding practices and the appropriate timing of introduction of complementary feeding, (2) estimated energy and nutrient requirements from complementary foods for children of different ages, and (3) available intervention strategies to encourage the recommended practices and ensure that young children consume adequate amounts of energy and nutrients during this particularly vulnerable period. We briefly describe the evidence supporting current feeding recommendations, the prevalence of recommended practices in low- and middle-income countries (LMICs), and examples of the potential impact of interventions to improve these practices.

Throughout the chapter, we adopt the infant and young child feeding

definitions proposed by the World Health Organization (WHO). In particular, “early initiation of breast-feeding” refers to breast-feeding within the first hour postpartum and “exclusive breast-feeding” refers to the consumption of no foods or liquids other than breast milk and possibly small amounts of medicines or vitamin–mineral supplements.[2] Infants are considered “predominantly breast-fed” when they occasionally receive small amounts of other liquids in addition to breast milk. The period of “complementary feeding” refers to the stage of infant and child feeding when other foods and/or energy-containing liquids are provided to the young child along with breast milk,[3] and “complementary foods” are the non-breast-milk components of mixed diets consumed by young children while they are still breast-feeding. In some situations, where breast-feeding is either temporarily interrupted or replaced due to pathological conditions of the mother or the infant or because the mother elects not to breast-feed, other dietary practices are necessary. Alternative feeding practices employing breast-milk substitutes are discussed in a separate chapter.

BREAST-FEEDING

Timing of Initiation

During the first 2–4 days of early lactogenesis, the mammary gland secretes colostrum, which is a concentrated mixture of essential nutrients, immunoglobulins, and other protective factors.[4] A recent observational study of more than 10,000 Ghanaian newborns who survived beyond the first day postpartum found a direct relationship between delays in the initiation of breast-feeding and the risk of newborn deaths during the period from 2 to 28 days postpartum. Initiation of breast-feeding after the first day was associated with a 2.4-fold increased risk of neonatal mortality compared with introduction on the first day, regardless of the type of breast-feeding practices (exclusive or nonexclusive). Introduction of prelacteal feeds (fluids or foods) before initiating breast-feeding was also associated with a significantly increased mortality risk; nonexclusively breast-fed infants had higher neonatal mortality rates than those who were breast-fed exclusively, even when controlling for the time of introduction of breast-feeding. These results indicate that both the time of initiation of breast-feeding and the type of breast-feeding practices affect neonatal mortality risk. The authors estimated that in this study population, in which approximately 40% of mothers started breast-feeding within one hour of delivery, the overall neonatal mortality rate from day 2 to 28

postpartum could be reduced by as much as 22% if all women would adopt the recommended practice of early initiation of breast-feeding.[5,6]

Early initiation of breast-feeding may protect the newborn via several possible mechanisms, including (1) enhanced milk production by the mammary gland and greater subsequent sustainability of exclusive breast-feeding; (2) accelerated maturation of the infant digestive tract and colonization by protective microbiota, thereby enhancing resistance to enteric infections; (3) protection from exposure to potentially contaminated liquids or breast-milk substitutes; and (4) reduced risk of hypothermia afforded by the close contact between mother and child.[4,5]

Statistics on the global prevalence of early initiation of breast-feeding indicate that fewer than half the infants born each year (42% globally in 2011, 52% in LMICs) are put to the breast within the first hour. The lowest rates of early breast-feeding initiation occur in South Asia (39%) and the highest in Eastern and Southern Africa (56%).[4]

Intervention strategies to promote early breast-feeding include (1) informing mothers about the benefits of early breast-feeding well before the anticipated delivery date, (2) assisting mothers to recognize when newborns are ready to start breast-feeding, (3) ensuring that health workers communicate and encourage mothers to start breast-feeding within the first hour, and (4) providing the same guidance regardless of whether the mother gives birth in a health facility or at home.

Key point

- Increases in early initiation of breast-feeding within the first hour postpartum can reduce neonatal mortality.

Duration of Exclusive Breast-Feeding

Compared with other forms of infant feeding, exclusive breast-feeding during the first half of infancy is associated with reduced risks of gastrointestinal, respiratory and other infections.[7–9] Consistent with these results from observational studies, a randomized trial to promote exclusive breast-feeding in India found that the prevalence of diarrhea was significantly less (relative risk = 0.64 [confidence interval: 0.44–0.95] at three months and 0.85 [CI: 0.72–0.99] at six months) in the intervention communities, where 79% of infants were exclusively or predominantly breast-fed at three months, compared to the control communities, where

only 48% of infants adhered to these feeding practices.[10] A pooled analysis of the relationships between infant feeding practices and mortality risk in six countries (Brazil, The Gambia, Ghana, Pakistan, the Philippines, and Senegal) found that infants who were not exclusively or predominantly breast-fed had an increased risk of dying, especially at younger ages (odds ratio = 5.8 [95% CI: 3.4–9.8] from 0 to 2 months, 4.1 [2.7 – 6.4] from 2 to 3 months, 2.6 [1.6 – 3.9] from 4 to 5 months, and 1.8 [1.2 – 2.8] from 6 to 8 months).[11]

During the first six months of life, exclusive breast-feeding provides sufficient water, energy, and macro- and micronutrients to satisfy the growth requirements of normal birth weight, term infants.[12,13] Several randomized trials have examined whether introduction of complementary foods before six months enhances the growth of infants from four to six months compared with exclusive breast-feeding for six months. According to studies conducted both in low-income countries (LICs; Honduras,[14,15] India[10]) and more affluent settings (Belarus;[16] Iceland[17]), earlier introduction of complementary foods does not promote greater growth rates. These results, combined with the aforementioned information on the beneficial effects of exclusive breast-feeding for reducing the risks of infant morbidity and mortality, provide the rationale for recommending exclusive breast-feeding until six months.[8]

Infants born to HIV-infected mothers face an increased risk of transmission of HIV infection through breast milk unless their mothers are taking antiretroviral therapy.[18] At the same time, because exclusive breast-feeding protects the infant from other infections, breast-feeding may still be more favorable for infant survival in many LMIC settings. In view of these trade-offs, in countries with high infant mortality rates WHO recommends “exclusive breast-feeding for HIV-infected mothers for the first six months of life unless replacement feeding is acceptable, feasible, affordable, sustainable and safe for them and their infants before that time.”[18] More information on feeding infants of HIV-infected mothers is presented in Chapter 46.

Prevalence of Exclusive Breast-Feeding in Low- and Middle-Income Countries

Despite the convincing scientific evidence on the protective role of exclusive breast-feeding, and the related WHO recommendations on infant and young child feeding practices, the prevalence of exclusive breast-feeding remains disappointingly low. The global prevalence of exclusive

breast-feeding until six months was 39% for the period from 2006 to 2010,[4] ranging from 25% in Western and Central Africa to 52% in Eastern and Southern Africa.[4] In many LMICs, administration of water and other non-milk liquids is common,[19] indicating that the rates of exclusive breast-feeding could be substantially improved just by eliminating these nonnutritive beverages. On the basis of the increased mortality risk of suboptimal infant-feeding practices and the current prevalence of these practices, the recent *Lancet* series on maternal and child nutrition estimated that approximately 800,000 child deaths a year (11.6% of total child deaths) are attributable to poor breast-feeding practices.[20]

Strategies to Promote Exclusive Breast-Feeding

Promotion of appropriate breast-feeding practices is possible through health system contacts, such as with the Baby-Friendly Hospital Initiative,[21] and community-based interventions, such as peer counseling groups.[22,23] A recent systematic review of the effects of breast-feeding promotion concluded that it is possible to achieve substantial increases in any breast-feeding and in exclusive breast-feeding at both 4–6 weeks and six months.[24] Both prenatal and postnatal counseling were deemed to be important to achieve maximum impact. Another review of this topic similarly concluded that using multiple channels of communication to reach caregivers and those who influence them yields greater impact than single channel approaches.[25] As one example, an effectiveness trial in India used multiple communication channels before and after delivery to promote appropriate breast-feeding practices, including monthly contacts by a nurse midwife, quarterly contacts by community health agents, and monthly meetings convened by a community representative.[10] The prevalence of exclusive breast-feeding reached 79% in the intervention communities, compared with 48% in the nonintervention communities, and was accompanied by reductions in diarrhea, as described above.

National policies need to be formulated to protect breast-feeding, for example, through adoption and implementation of the International Code of Marketing of Breast-milk Substitutes.[26] Protection of breast-feeding is particularly challenging in LMICs because of limited systematic oversight of private sector marketing practices. Regrettably, studies continue to show that health workers accept free samples of milk and other gifts from unscrupulous companies that inappropriately market breast-milk substitutes and/or help disseminate misleading or incorrect infant feeding information produced by these companies.[27–29] It is also important to

recognize the critical roles of government and civil society in supporting appropriate infant and young child feeding practices. A recent systemic review indicated that there are failures at multiple levels of the monitoring and control process, which need to be addressed by more effective government activities and participation of key stakeholders.[30,31]

Effect of Maternal Nutritional Status and Dietary Intake on Breast-Milk Volume and Composition

Studies show that unless a woman is severely wasted (i.e., chronically energy deficient with a body mass index [BMI] <18.5 kg/m^2),[32] she is generally able to produce an adequate volume of milk. For example, studies of low BMI Bangladeshi women (mean BMI 17.8 kg/m^2) found that they produced an average of 750 mL/d of breast milk when their infants were 5–7 months of age,[33] which is similar to reports from more affluent countries (Sweden,[34] USA[35]). Protein and carbohydrate contents of mature human milk are largely unaffected by maternal nutritional status and diet.[33,36] Milk fat content (and, thus, milk energy content) is lower in thin women; however, infants who are allowed to nurse on demand generally compensate for this by consuming a higher volume of milk.[3] Although the protein content of human milk is considerably less than in cow milk, protein is not a limiting factor in the growth of exclusively breast-fed infants. In a randomized trial in Honduras, infants who continued to be exclusively breast-fed from four to six months had the same growth pattern as infants who were given additional foods that provided 20% more total daily protein intake, thus demonstrating that the lower protein intake associated with exclusive breast-feeding does not limit infant growth.[3,37]

Whereas some vitamins and minerals are excreted in mature breast milk in relation to maternal nutritional status and dietary (or supplement) intake, others are secreted in regulated amounts, regardless of maternal nutritional conditions. The former set of nutrients, that is, those that are affected by maternal body stores and dietary intake, are vitamin A, thiamin, riboflavin, vitamin B6, vitamin B12, iodine, and selenium. Maternal dietary deficiency of these nutrients reduces their concentrations in milk and may adversely affect infant nutritional status and health (e.g., resulting in infant beriberi in case of maternal thiamin deficiency[38] or increased risk of night blindness and xerophthalmia in case of vitamin A deficiency[39]). The concentration of these nutrients in breast milk can be rapidly restored by increasing maternal intake. The second set of nutrients,

which are not affected by maternal intake or stores, are calcium, copper, iron, zinc, folate, and vitamin D. Although maternal deficiency of these micronutrients does not affect their excretion in breast milk, continued breast-feeding may contribute further to the woman's poor nutritional status. Thus, maternal supplementation with these nutrients is more important for the mother's nutritional adequacy than for her infant's.[3]

Summary information on average breast milk nutrient composition of presumably well-nourished U.S. women is presented in Table 41-1, based on a report prepared previously by the U.S. Institute of Medicine.[40] As indicated in the table, the iron content of mature human milk is very low. Nevertheless, infants are able to draw on tissue iron reserves accumulated during fetal life, so normal-weight term infants generally have adequate iron status at six months. However, small-for-gestational-age and premature infants often require iron supplements before six months to prevent iron deficiency anemia.[41] Another approach to preventing iron deficiency in young infants is to avoid premature clamping of the umbilical cord at the time of delivery.[42]

The zinc content of human milk is relatively high during the first few months postpartum, but declines to fairly low levels thereafter.[43] Nevertheless, the combination of breast milk and newborn hepatic zinc reserves supplies all of the theoretical zinc needs for at least the first several months of life. Recent WHO guidelines no longer recommend early postpartum maternal vitamin A supplementation for the prevention of maternal and infant morbidity and mortality because of weak evidence of efficacy.[44] However, these guidelines do not address the effect of maternal vitamin A supplementation on breast milk vitamin A content, which may benefit infant vitamin A status.[39,45]

Exclusively breast-fed infants of mothers who are complete vegetarians or whose diet is very low in animal-source foods may exhibit signs of vitamin B12 deficiency. Direct supplementation of lactating women does not seem to increase breast milk vitamin B12 content substantially,[46] so it may be necessary to initiate maternal supplementation before or during pregnancy or provide parenteral vitamin B12 if the deficiency is pronounced. Information on the risk of other specific micronutrient deficiencies during the period of exclusive breast-feeding is generally limited; and, as described above, may depend in part on maternal nutritional status and related aspects of breast milk composition.

TABLE 41-1 Average Protein and Micronutrient

Composition of Mature Human Milk[3]

Nutrient	Amount in Mature Human Milk
Protein (g/L)	10.5 ± 2.0
Folate (µg/L)	85 ± 37
Niacin (mg/L)	1.50 ± 0.20
Riboflavin (mg/L)	0.35 ± 0.025
Thiamin (mg/L)	0.21 ± 0.03
Vitamin B_6 (µg/L)	93 ± 8
Vitamin B_{12} (µg/L)	0.97
Vitamin A (µg retinol equivalents/L)[47]	500
Vitamin D (µg/L)	0.55 ± 0.10
Calcium (mg/L)	280 ± 26
Iron (mg/L)	0.30 ± 0.10
Zinc (mg/L)[a]	1.2 ± 0.2

[a] The figure 1.2 mg Zn/L refers to early lactation. A recent review concluded that the zinc concentration of human milk declines during the first few weeks and months following delivery, with average values of 0.93 ± 0.58 mg/L at 6-8 months and 0.77 ± 0.51 mg/L at 9 months post-partum.[43]

Key points

- In LMICs, exclusive breast-feeding for six months decreases the risk of diarrhea and other infections compared to earlier introduction of complementary feeding or discontinuation of breast-feeding.
- Exclusive breast-feeding during the first 6 months of life and continued breast-feeding up to 2 years of age is associated with a decreased risk of under-5 mortality.
- There is no evidence of enhanced growth when complementary foods are introduced before six months.
- These combined sets of information indicate that exclusive breast-feeding during the first six months postpartum and continued breast-feeding thereafter should continue to be supported as public health policy in both low-income and more affluent countries.
- Pre- and postnatal counseling via multiple channels of communication can increase appropriate breast-feeding practices.
- In undernourished mothers, maternal dietary supplementation

may be advisable, both to optimize breast milk nutrient concentrations and to prevent further maternal depletion.

COMPLEMENTARY FEEDING IN LOW-INCOME COUNTRIES

Complementary Feeding

As children reach approximately 6 months of age, breast milk alone may no longer satisfy energy and nutrient needs of the growing infant, so complementary feeding needs to be initiated. Complementary feeding refers to the consumption of both breast milk and other foods, usually during the period from 6 to 24 months of age, until the child ceases to nurse at the breast, at which time the child is usually consuming the same foods as the rest of the family. Complementary food is defined as any non-breast milk foods or nutritive liquids that are given to young children during this period of complementary feeding.[3]

Despite current WHO recommendations that infants should begin receiving nutritionally adequate and safe complementary foods at six months of age,[3] global data collected from 2007 to 2011 indicate that only 60% of children had started receiving soft, semisolid, or solid food by 6–8 months of age.[4] For example, Figure 41-1 portrays the actual child feeding practices in Nigeria compared with the scenario recommended by WHO. The Nigerian data indicate that a sizeable proportion of infants fail to receive adequate complementary foods from 6 to 11 months of age, and a large number are weaned from the breast prematurely.

Energy Requirements From Complementary Foods

The average amount of energy that should be provided from complementary foods has been calculated for children of different ages based on differences between their average energy requirements and the average amount of energy provided by breast milk. Energy requirements of children of different ages have been estimated from direct measurements of energy expenditure and the amount of energy contained in newly accrued tissue. The average amounts of energy provided by breast milk were determined using pooled data from breast-fed children in low-income countries.[3] The amounts of energy provided by breast milk were then subtracted from the amounts of energy required by children in each age group to determine the average amounts of energy needed from

complementary food. According to these calculations, the average amounts of energy required from complementary food are approximately 200, 300, and 550 kcal/d for infants 6–8, 9–11, and 12–23 months of age, respectively (Table 41-2).[48]

Several caveats must be recognized in using these estimates. First, there is considerable interindividual variation in young children's energy requirements, so the needs of specific children may differ substantially from the average value. Second, the volume and composition of breast milk vary among women. Thus, the total amount of energy provided to the child from complementary foods may need to be adjusted according to the child's usual level of consumption and pattern of growth, although the average figures can be used as a first approximation of the child's needs.

Energy Density and Frequency of Feeding Complementary Foods

The total daily amount of energy consumed from complementary foods is a product of the frequency of feeding (number of servings per day), the amount of food provided and the energy density of these foods (kcal/g prepared food weight) (Figure 41-2).[3] Using this combined set of information, it is possible to formulate appropriate complementary foods to satisfy daily energy requirements of children of different ages (Table 41-3). As indicated in the table, when a child is served complementary foods fewer times per day, the foods must be of greater energy density to achieve desired levels of energy intake, and vice versa. Guidelines are available on the appropriate frequency of feeding complementary foods for children of different ages.[1]

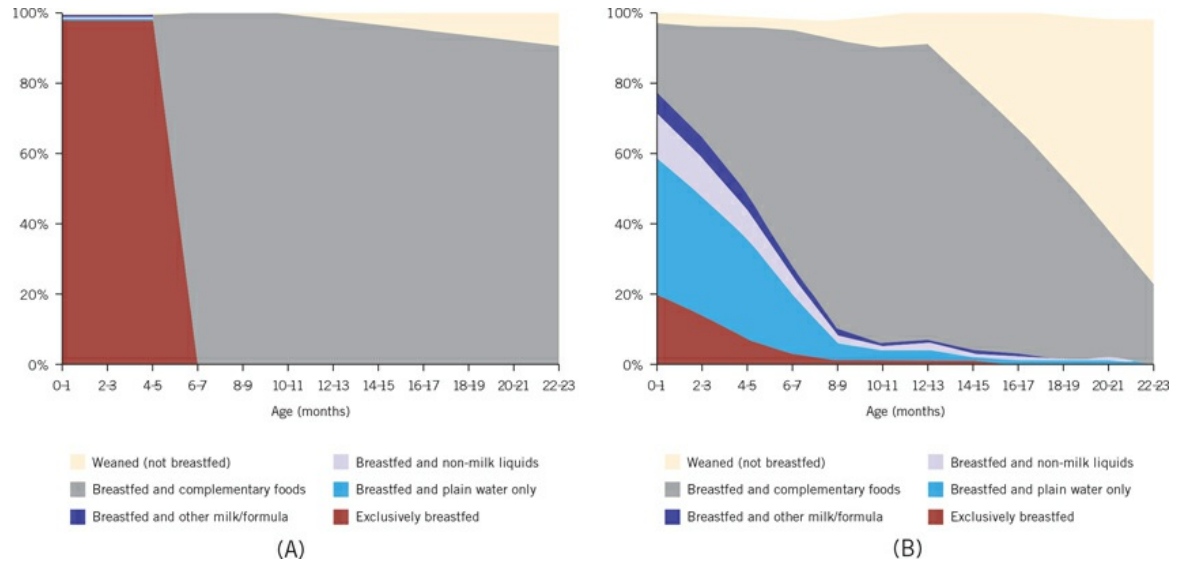

Figure 41-1 Timing of introducing complementary feeding. A, The scenario recommended by WHO. B, Suboptimal scenario (case of Nigeria).[4]

TABLE 41-2 Average Amount of Energy (kcal) Needed From Complementary Food as Function of Energy Content of Breast Milk Fed to Children in Low-Income Countries, by Age Group

	Age Group (Months)		
Energy requirements and energy sources	**6–8**	**9–11**	**12–23**
Average total energy requirement (kcal/d)	615	686	894
Average amount of energy transferred from mother to infant in breast milk (kcal/d)	403	379	346
Average amount of energy required from complementary foods (kcal/d)	212	307	548

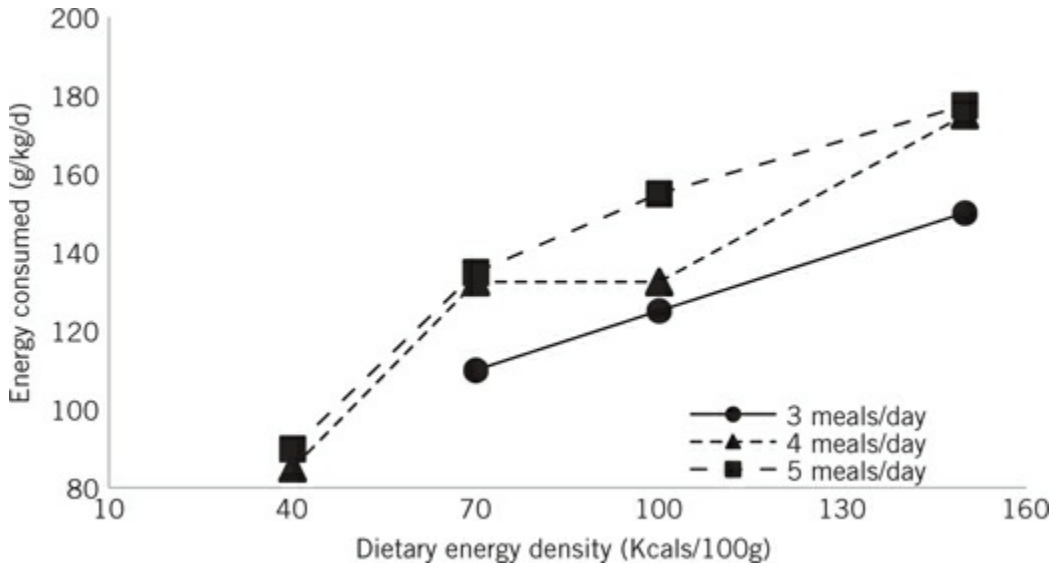

Figure 41-2 Effects of dietary energy density and frequency of feeding on total daily energy intakes by young children (6–18 months of age) recovering from severe malnutrition.[3]

TABLE 41-3 Minimum Dietary Energy Density Needed to Satisfy Energy Requirements from Complementary Food at Different Ages According to the Number of Meals Served Per Day[a]

	Energy Density (kcal/g Food) by Age Group (Months)		
Number of Meals	**6–8**	**9–11**	**12–23**
2	0.71	0.84	1.12
3	0.48	0.56	0.75
4	0.36	0.42	0.56
5	0.29	0.34	0.45

[a] Values estimated based on average level of breast milk intake and assumed gastric capacity of 30 g/kg body weight in each age group.

Key point

- Complementary food of sufficient energy density should be offered an age-appropriate number of times per day, beginning at 6 months of age.

Concerns have been raised that providing high-energy-density complementary foods could displace breast milk intake or reduce the duration of breast-feeding. For example, a study carried out among healthy breast-fed children in Bangladesh found slightly lower breast milk intakes when high-energy-density foods were provided, although total energy intake was greater.[49] By contrast, a recent study, which provided small quantity lipid-based nutrient supplements to breast-fed children, found no effect on breast milk intake.[50] Thus, more information is needed on this issue.

Nutrient Requirements From Complementary Foods

The same approach used for calculating the energy needs from complementary foods can be used for estimating the requirements for individual nutrients. In particular, the average amount of each nutrient that is, provided by breast milk is subtracted from the total dietary requirement to determine the amount needed from complementary foods at different ages, as described in the following sections. For these analyses, nutrient intakes from breast milk were estimated based on breast milk content for women in affluent countries (nutrient concentration of mature milk multiplied by the appropriate breast-milk volume), with the exception of vitamin A, where estimates are available from low-income countries.[3]

Nutrient Requirements of Infants and Young Children

Several expert committees of the United Nations and the U.S. Institute of Medicine (IOM), among others, have developed estimates of young children's nutrient requirements, as summarized in Table 41-4. Regrettably, there are discrepancies in the methods used by the different committees to derive these requirements and in their resulting recommendations, so it is not yet possible to achieve full consensus on the appropriate nutrient contents of complementary foods. The IOM report generally estimated adequate intakes (AIs) for infants between 7 and 12 months of age, based on mean observed intakes of healthy U.S. infants.[48] This approach is not ideal, however, because many of the infants whose intakes were observed may have been consuming considerably more than

their true requirements, so the estimates may be unnecessarily high. For children between 13 and 23 months, the IOM generally estimated dietary requirements based on extrapolation from values for older children or adults or by using a factorial method. Because of the inconsistent methods used for different age groups, there are some counterintuitive reductions in estimated requirements as children become older. The most recent WHO estimates published in 2002 adopted many, but not all, of the recommendations published by the IOM, so some discrepancies in the different estimates still remain. The reasons for these discrepancies and implications for estimated nutrient requirements from complementary foods have been discussed in more detail by Dewey and Brown.[48]

Nutrient Requirements From Complementary Foods

As indicated above, nutrient requirements from complementary foods can be calculated as the difference between the total nutrient requirement and the amounts of these nutrients transferred from the mother to the child in breast milk.[51] These requirements can then be expressed in terms of desirable nutrient densities of complementary foods (amount/100 kcal), by dividing the age-specific amounts of each nutrient required in complementary foods by the respective average amount of energy required from these foods. Examples of these recommended nutrient densities of complementary foods for children of different ages are shown in Table 41-5, by age group and source of estimated nutrient requirements. Despite the aforementioned discrepancies in estimated nutrient requirements, desirable nutrient densities based on the IOM and WHO recommendations are reasonably consistent for protein, iron, riboflavin, thiamine, niacin, folate, and pyridoxine. However, there are large discrepancies for vitamin A and C, calcium and zinc, mainly because of the different approaches used to estimate these requirements.

Problem Nutrients in Complementary Foods and Strategies to Achieve Adequate Nutrient Intakes

Problem nutrients are those for which there is the greatest discrepancy between the estimated amount required by the child and their content in complementary foods.[3] The problem nutrients can be identified by comparing the estimates of desirable nutrient density of complementary foods (amount of nutrient/100 kcal) with the actual nutrient densities of the foods consumed by breast-fed children in various populations.[48] Analyses of dietary intake data from multiple LICs indicate that iron, zinc, calcium, selected B vitamins, and sometimes vitamin A may be present in

inadequate amounts in traditional, home-available complementary foods.[48,52]

Consistent with the data on micronutrient inadequacy of traditional complementary feeding regimens, limited global data on the prevalence of micronutrient deficiencies indicate that deficiencies of zinc, iron, vitamin A, and others are common among young children in LICs.[53,54] Thus, more effort is needed to improve the micronutrient quality of complementary foods or supply the missing nutrients in other forms. Available strategies to supply "problem nutrients" include promotion of a diversified diet, with generous intake of animal-source foods; provision of fortified, processed complementary foods; delivery of nutrient supplements through home-based fortification or supplementation or through biofortification of commonly consumed foods. The following sections briefly describe each of these approaches.

DIETARY MODIFICATION AND DIVERSIFICATION

Methods have been described to identify locally available, affordable foods that can supply problem nutrients, based on the results of quantitative dietary intake data and application of linear programming techniques. Relevant information on the data needs and modeling procedures for this approach is available through the PROPAN website.[55] In general, adequate intake of many of the problem nutrients described above can be achieved only by incorporating animal-source foods, such as animal flesh and organs, dairy products, eggs and fish, into the diet. Animal flesh foods are excellent sources of highly bioavailable heme iron and zinc, along with a number of B vitamins, so inclusion of these foods in young children's diets should be encouraged. These foods are also rich in high-quality protein, although traditional complementary feeding regimens generally contain adequate amounts of protein, unless they are composed mainly of low-protein tubers, such as cassava or sweet potato, or refined starches.

The availability of animal-source foods may be very limited in the poorest countries,[56] and their relatively high cost frequently limits the amounts consumed in poorer households. Moreover, religious proscriptions or cultural taboos may prevent their use in some societies. Nevertheless, if these foods are adequately cooked and finely minced, experience shows that they can be consumed without difficulty by young

children. Recent studies in both the United States and a number of LICs have demonstrated the feasibility of including meat in the feeding regimens of young infants.[57] Another study carried out in slum communities in Peru, found that, following an intensive educational campaign, even poor households were able to increase children's consumption of animal-source foods, and the linear growth of children in the intervention communities was significantly greater than in the control areas, reducing the rate of stunting at 12 months by two-thirds.[58] Thus, it may be possible to increase children's consumption of these foods in some settings, by using appropriately targeted educational interventions.

TABLE 41-4 Nutrient Requirements, by Age Group Based on the WHO/United Nations Children's Fund (UNICEF) 1998 Complementary Feeding Report[3], the IOM Dietary Reference Intakes (DRI) and WHO/Food and Agriculture Organization 2002 Recommendations[48]

Nutrient	Age 6–8 Months			Age 9–11 Months			Age 12–23 Months		
	WHO/ UNICEF 1998	New DRI	WHO 2002	WHO/ UNICEF 1998	New DRI	WHO 2002	WHO/ UNICEF 1998	New DRI	WHO 2002

[a]Assumes medium iron availability (10%).

[b]Excluding the contribution of dietary tryptophan to niacin synthesis.

[c]Corrected value.

Nonhuman animal milks and related dairy products, such as yogurt and some cheeses, are alternative sources of selected problem nutrients. These foods are rich in calcium and several B vitamins, but low in iron unless fortified. Moreover, if milk products are not properly heat-treated, they can cause gastrointestinal bleeding in infants, causing a further threat to their iron status.[59] Furthermore, because of the relatively high total fat and saturated fatty acid contents of these products, some authorities recommend using partially skimmed milk.[60] However, there is little evidence of any long-term adverse effects of milk fat intake in early childhood on the subsequent risk of cardiovascular disease, so some child feeding guidelines suggest that reduced fat milks should not be introduced before 2–3 years of age to limit the possibility of inadequate energy intakes.[61]

CEREAL PRODUCTS

Cereal products are commonly used as a major component of complementary feeding regimens. Such foods provide energy, mostly as carbohydrate, and they contribute some protein. However, cereal protein is

limited in certain amino acids (e.g., lysine in wheat and rice and lysine and tryptophan in maize), compared with reference protein (egg albumin or milk protein); the digestibility of cereal proteins is generally less than that of proteins derived from animal-source foods. For these reasons, total protein intakes from cereals must be adjusted for their equivalent amount of reference protein, as described by the Food and Agriculture Organization (FAO).[62] Nevertheless, as indicated above, protein intake is usually sufficient from most complementary feeding regimens that have been examined. Although cereals provide essential minerals, especially when consumed as whole-grain products, concerns have been raised about mineral bioavailability from these foods because their high phytate content can inhibit mineral absorption. However, a recent study of Swedish infants who were randomly assigned to receive cereal-based diets with and without phytate reduction from 6 to 12 months of age found no long-term differences in their iron or zinc status.[63]

PROCESSED COMPLEMENTARY FOODS

Distribution of processed, fortified complementary foods, either through public sector programs or through commercial channels, offers an alternative food-based approach to supply problem nutrients.[64] Although such foods can successfully cover current nutrient shortfalls of the home diet, the rapid changes in young children's nutrient requirements during the period of complementary feeding make it difficult to design a single product that meets the nutrient needs of all children in this age range without imposing the risk of excessive intakes by some children.[65] Moreover, the impact of these foods on children's growth has been inconsistent, possibly related to the timing, amount, and composition of these foods, as well as the underlying nutritional status and frequency of infections of the study populations.[66–68] Despite the inconsistent growth responses observed in these earlier studies, several recent studies have found positive effects on iron status and/or developmental milestones among children who received these products.[69–71]

MICRONUTRIENT SUPPLEMENTS

Addition of micronutrients to current feeding regimens, either through home-based food fortification or direct child supplementation, offers a lower cost strategy than providing a processed, nutritionally complete

complementary food. Home-based fortification involves the addition of a prepackaged micronutrient supplement to the child's food one or more times daily at the time of serving. One such formulation, based on a micronutrient powder containing iron as microencapsulated ferrous fumarate (to avoid adverse organoleptic effects of iron on food) and vitamins A and D, folic acid, ascorbic acid, and zinc, has been shown to reduce rates of anemia among consumers, although evidence of its positive impact on other indicators of micronutrient status and growth are still lacking.[72] WHO concluded that there is strong evidence on the effects of home fortification of complementary foods with micronutrient powders (MNPs) for children aged 6–23 months on their nutritional, health, and development outcomes.[73] Thus, WHO recommends the use of MNPs to improve iron status and reduce anemia among infants and children 6–23 months of age.[74]

Another approach to home fortification uses small-quantity lipid-based supplements, which are usually prepared with peanut paste, vegetable oil, protein concentrate (milk powder or soy), and multiple micronutrients.[75] Recent studies in West Africa have found greater linear growth and earlier achievement of developmental milestones among young children who received these products.[76,77] Micronutrient supplements also may be supplied as liquid formulations or chewable, crushable, or dispersible tablets.[78] A complete review of these products and related issues is beyond the scope of the present chapter. Nevertheless, each of these formulations has been found to yield positive impacts on selected indicators of micronutrient status, depending on the specific formulation, the preexisting nutritional status of the target population and the presence of conditions that may interfere with nutrient absorption or utilization; but there is only limited evidence of any positive effects of these products on child growth. On the other hand, some studies have detected adverse effects of iron supplements and iron-containing micronutrient powders on risk of infectious diseases and related hospitalizations,[79–81] especially among iron-replete individuals, so WHO recommends that these products should be used only where iron deficiency is common and in the context of infection control programs.[82] Additional research is required to define optimal dosing regimens of such multiple micronutrient formulations added to complementary foods, interactions among nutrients in the various preparations, and any possible adverse effects on child growth and other health outcomes in particular settings.

BIOFORTIFICATION

Biofortification is a process whereby the density of minerals and vitamins of individual crops can be increased through conventional plant breeding or the use of transgenic techniques. To date, most biofortification programs have focused on increasing the iron, zinc, or provitamin A contents of staple foods. One of the most successful programs is currently promoting greater production and consumption of orange-fleshed sweet potato, which is a rich source of the vitamin A precursor beta carotene. Introduction of orange-fleshed sweet potato in rural Mozambique, along with feeding advice, resulted in a considerable increase in vitamin A intakes compared to the nonintervention group and a reduction in the prevalence of vitamin A deficiency.[83] More information on the scope and future potential of biofortification is available through existing reviews of this topic.[83–85]

SAFE PREPARATION OF COMPLEMENTARY FOODS

An important contributor to growth faltering among children 6–23 months of age in LICs is the high incidence of enteric infections and environmental enteropathy,[86,87] some of which is due to food-borne infections. Thus, improving the hygienic quality of complementary foods may be just as important as focusing on their adequate nutritional quality. A study examining the microbiological quality of complementary food in rural and urban areas in Bangladesh, for example, found that 40% of the complementary foods contained *Escherichia coli*, an indicator of fecal contamination.[88] Poor hygienic conditions during preparation and serving were highly related to food contamination. Moreover, storing the food at ambient temperatures between meals and consumption of contaminated complementary foods were associated with a higher frequency of diarrhea. Contaminated feeding bottles are a particularly important source of pathogen transmission. In periurban Peru, for example, 35% of bottle nipples were contaminated with *E. coli*, and 31% of teas served in bottles were contaminated compared to just 2% when teas were served in cups.[1]

The Pan American Health Organization/WHO recommends the following food hygiene practices when preparing, serving, and storing complementary foods: (1) hand washing of both caregiver and child before food preparation and feeding; (2) serving food immediately after preparation, and/or storing the food properly at sufficiently low or high

temperatures to prevent microbial proliferation; (3) using clean serving utensils; and (4) avoiding feeding bottles in settings where quality of water is poor and chemical and/or thermal treatments are not easily accomplished. Several interventions that have proved to be effective in improving the microbiological quality of complementary food are caregiver education on good hygienic practices, and improving traditional food storage and processing methods (e.g., by using food fermentation).[89]

INTERVENTIONS TO IMPROVE COMPLEMENTARY FEEDING PRACTICES

The range of intervention programs to promote enhanced complementary feeding practices and information on their impact on children's growth have been described in several systematic reviews.[67,90,91] Intervention strategies that were examined include behavior change/communication interventions to encourage improved feeding practices and/or energy density, provision of processed complementary foods and distribution of different forms of added micronutrients. In general, the average effect sizes of these interventions on children's growth were fairly small (effect sizes ~0.2–0.3 SD units) and did not differ by intervention strategy. These results suggest that enhanced growth is possible through improved complementary feeding, but feeding alone may not fully ameliorate growth restriction unless prenatal factors contributing to growth restriction[92,93] and postnatal infections are also addressed.[94]

Key points

- Despite uncertainty regarding the nutrient requirements of infants and young children, recommendations have been developed on the minimum adequate nutrient density of complementary foods for children of different ages.
- Iron, zinc, calcium, selected B vitamins, and vitamin A are often present in inadequate amounts in traditional complementary feeding regimens.
- Feeding a variety of foods, including animal-source foods, particular fruits and vegetables, and biofortified foods can improve micronutrient intake from complementary foods. When suitable low-cost local diets cannot be prepared from acceptable, locally available foods, home fortification and

nutrient supplementation provide other options to achieve adequate nutrient intakes.

- A variety of intervention strategies can be used to enhance complementary feeding practices; but additional interventions, including postnatal infection control, may be necessary to allow children to meet their growth potential during the period of complementary feeding.

SUMMARY

Increased information on the multiple advantages of exclusive breast-feeding during the early months of life, the optimal timing of introduction of complementary foods, and the appropriate energy density, feeding frequency, and micronutrient composition of these foods has become available in recent years. Relevant feeding guidelines have been disseminated and intervention strategies tested and promoted. However, complete understanding of the effects of different complementary feeding regimens on breast milk intakes and the ultimate duration of breast-feeding is still lacking. Likewise, more information is needed on the ideal micronutrient composition of fortified complementary foods, the design of integrated nutrition and infection control programs and the impact of alternative micronutrient delivery systems on young children's nutritional status, physical growth, and neurobehavioral development.

Child Nutrition and Economic Development

William A. Masters, PhD

Children's nutrition is both cause and consequence of broader health conditions, household income, and living standards. This chapter describes the principal changes in child nutrition that have been associated with economic development across countries in recent decades, summarizing newly available data on anthropometric status, breast-feeding, and food consumption, as well as other influences on nutritional balances such as sanitation and disease prevention. Some of these changes are mediated by national or community-level policies and programs as well as medical interventions described elsewhere in this text, but most of the patterns described in this chapter occur autonomously as individuals respond to changing circumstances associated with economic development. These changes often occur slowly, without the conscious knowledge of those involved, and have only recently been documented thanks to the accumulation of evidence from a wide range of social environments.

IMPROVEMENTS OVER TIME AND COMPARISONS ACROSS COUNTRIES

Leo Tolstoy's classic novel *Anna Karenina* begins: "All happy families are alike; each unhappy family is unhappy in its own way." This claim starts an epic, questioning search for whatever it might be that successes have in common. For economic development, a large social science literature documents wide variation in peoples' living conditions. These

circumstances have often stagnated for centuries, with almost all people experiencing relatively poor health, low income, and less preferred living standards, until new opportunities and forms of social organization trigger the onset of sustained improvement.[1] Rising income is eventually associated with large gains in adult height, weight, and many measures of health[2] and even measureable increases in subjective well-being.[3] It turns out that success in one dimension is typically accompanied by successes in other areas. Many different obstacles might slow development, but successful societies often move in similar directions as people gradually achieve similar objectives.

In this chapter, we focus on changing child nutrition, which is among the most universal human goals that economic development can help people pursue.[4,5] We describe how child nutrition alters during economic development, defined very broadly to mean households' overall purchasing power over real goods and services. Households vary in how they acquire that purchasing power, which comes from labor earnings, home production, and wealth of all kinds. Household purchasing power is measured as the sum of all income sources, adjusted for local prices in each year. For this calculation, we use the Penn World Tables (PWT), which offers the world's broadest and most complete set of real income data, updated regularly by the Center for International Comparisons of Production, Income and Prices at the University of Pennsylvania. We use PWT version 7.1, based on national accounts and price data from 146 countries between 1950 and 2010.[6]

Many aspects of child nutrition are likely to change as their families acquire more purchasing power; here, we focus only on what is most widely measured. Surveys of several million children from more than a hundred countries over multiple decades allow us to look systematically at changes in child height, stunting, and wasting, as well as various contributors to nutritional status including food availability and diet quality, sanitation and water supplies, breast-feeding behavior and treatment of childhood diarrhea, vaccination and vitamin A supplementation. Each of these measures reflects a different aspect of child nutrition that is discussed only briefly here, and analyzed at greater length in other chapters.

To describe changes during economic development, we compare the various child nutrition indicators to average real income per person in each country, at the time of observation. National income is an aggregate measure of all economic activity, but structural changes within society also matter. We end the chapter with a discussion of two structural changes that

are particularly important for child nutrition: agricultural transformation (a shift from food production to other enterprises) and demographic transition (a shift from large to small families). These are closely related to each other and to average national income, and to a multitude of other social and institutional changes in gender relations, education, and child care practices.

Our focus in this chapter is on changes over long periods and differences among very diverse countries, using national averages and prevalence rates as indicators of how populations differ from each other. Variation within a given country is itself of interest but is addressed primarily elsewhere. The one distributional issue of great concern here is the fraction of children in the country who fall below a clinical threshold of severe malnutrition. The economic-development counterpart of this is the fraction of households that fall below a poverty line. A long literature in economics concerns how increases in average income affect the prevalence of poverty, and the same methods have now been applied to changes in malnutrition.[7]

Many factors other than economic development clearly matter for child nutrition. Ethnographic studies describe in detail how children are raised, finding that social norms and beliefs can lead to a variety of choices regarding complementary feeding and other nutritional practices.[8,9] These norms may eventually adjust to income changes, or may introduce variation that is unrelated to economic circumstances. Either way, by assembling data from millions of children around the world, we can look over a wide enough range of circumstances to see patterns that would otherwise be hidden. This chapter is descriptive, aimed at revealing stylized facts about long-term relationships. Once those facts are known, other techniques would be needed to address causality. In particular, for this chapter, we are looking at contemporaneous correlation, recognizing that this misses the time delays that play a major role in any underlying causal mechanisms.[10]

For visual clarity, our description of the evidence uses scatter plots and regression lines of each child nutrition indicator against the natural log of real income. This approach transforms exponential relationships into linear ones, and allows us to span the full range of purchasing power which varies from US$180 per person per year (a log value of 5.2) in Liberia and the Democratic Republic of Congo during their years of civil war, to above US$60,000 (a log value of 11) in Qatar and the United Arab Emirates during their years of highest oil revenue. The regression line traces the average change in each nutrition indicator associated with a constant 1%

change in purchasing power, while the scatter of individual observations reveals the pattern of variation around that central tendency. Systematic nonlinearities are often visible, for example, if observations cluster below or above particular parts of the regression line, and the overall variance or precision is shown by a 95% confidence interval around the regression's estimated mean at each income level. The resulting figures reveal long-term, cross-country patterns that could not be seen within individual countries or shorter time periods.

ANTHROPOMETRIC FINDINGS AND ECONOMIC DEVELOPMENT

Child Height, Stunting, and Wasting

Until very recently, the anthropometric data used to study nutrition in economic history referred mainly to adolescents and adults, whose heights were often measured for military or other institutional purposes.[2] Only since the 1990s have large-scale anthropometric surveys of children in developing countries obtained sufficient sample sizes to identify variation in the first years of life. Among the first striking results was that the growth faltering associated with undernutrition actually occurs very early in infancy and early childhood, mostly prior to age 2.[11] The most widely reported data typically refer to children from birth to age 5, and have been assembled from the pioneering Demographic and Health Surveys (DHS) funded by United States Agency for International Development (USAID), as well as the Multiple Indicator Cluster Surveys (MICS) of United Nations Children's Fund (UNICEF) and other sources.

We begin our description of the data with the broadest possible coverage of countries and years, using estimates provided by the Nutrition Impact Model Study (NIMS).[12] They compute nationally representative height and weight distributions for children under 5 across 141 developing countries, interpolating between surveys for annual data from 1985 to 2011 to measure progress over time.[13] Here, we extend their analysis to correlations with income, by combining these estimates with the PWT 7.1 measure of each country's real purchasing power. We begin with average heights, and then consider the prevalence of stunting and wasting using the smaller sample size of actual surveys starting in 1966 from the WHO Global Database on Child Growth and Malnutrition.[14]

For each anthropometric measure, we show a scatter plot of each observation against the log of real income per person. The observations are

drawn in two different shadings, one for the most recent decade (2000–2010) and one for earlier years, with separate regression lines that show a 95% confidence interval. This presentation is in the tradition of Samuel Preston who used a somewhat similar diagram to show how life expectancy at each income level changed over successive decades.[15] A shift in such Preston curves would be associated with variables other than contemporaneous income, and could include the cumulative effect of past income, new technologies, or changed policies and institutions.

Figure 42-1 shows the correlation between average real income per person and average child height, for the 137 countries that are in both the NIMS and PWT datasets, from 1985 (when NIMS data begin) to 2010 (when PWT data end). We have a total of 3485 country-year observations, based on underlying data from over 7.7 million survey subjects.[13] On this scatter plot, a few outlier countries can be seen trending over time. For example, the series of observations that crosses the -2 line at a log income level of about 9 is Guatemala, a country with famously poor nutrition outcomes given its income level.[16] This chart reveals that Guatemala has recently been converging toward the levels achieved elsewhere, as both income and height have risen sharply and moved closer to the regression line.

The regression lines in Figure 42-1 suggest that a very poor country with a log income around 6 (US$400 per person, per year) can be expected to have a mean height-for-age z score around –2. In other words, their average child would be shorter than 97.5% of children in the WHO's global reference population. At the highest income levels in this sample (Qatar and UAE), the average child is still shorter than the WHO reference median, which could be because this sample includes only "developing" countries, all of whom had relatively low incomes in the recent past. Comparing the two regression lines, average child heights at each income level are significantly higher in the most recent decade than in previous years. This could be because of a cumulative lagged effect of income itself, or to omitted variables that improve over time, such as innovations in health care, improved access to medical care, child health norms, and nutritional innovations of all kinds.

Figure 42-2 shows the prevalence of stunting, as the fraction of children with HAZ scores below –2. The regression line shows that at the world's lowest income levels, roughly half of children can be expected to be stunted. As with Figure 42-1, the scatter plot shows a clear association and also an improvement over time in the position of the regression line: at low income levels, fewer children were stunted in the 2000s than in

previous decades. Like Figure 42-1, the regression lines converge and are not significantly different from each other at high income levels. Also, nonlinearity in the scatter plot data is readily apparent in these data, as the richest of these developing countries have brought their stunting rates down close to the level seen in the WHO's reference population itself. Curvature of the scatter plots around the linear regression line is consistent with the result found elsewhere that a given percentage increase in income is most powerful in reducing malnutrition in poor countries with widespread undernutrition, while similar improvements in countries that have already made progress would require more targeted programs.[7]

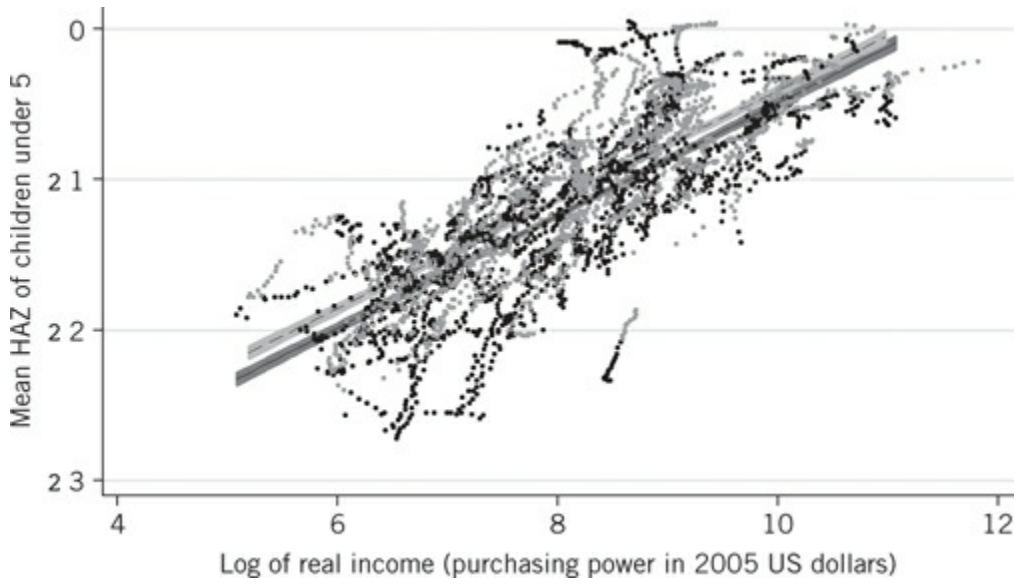

Figure 42-1 Child height and real income, 1985–1999 and 2000–2010 (Ezzati et al estimates, *N* = 3485 from 137 countries).

Note: Data shown are for 1985–1999 (darker shading) and 2000–2010 (lighter shading), with 95% confidence intervals around linear regressions. Sample sizes are *N* = 1978 across 137 countries for 1985–1999 and *N* = 1507 across 138 countries for 2000–2010.

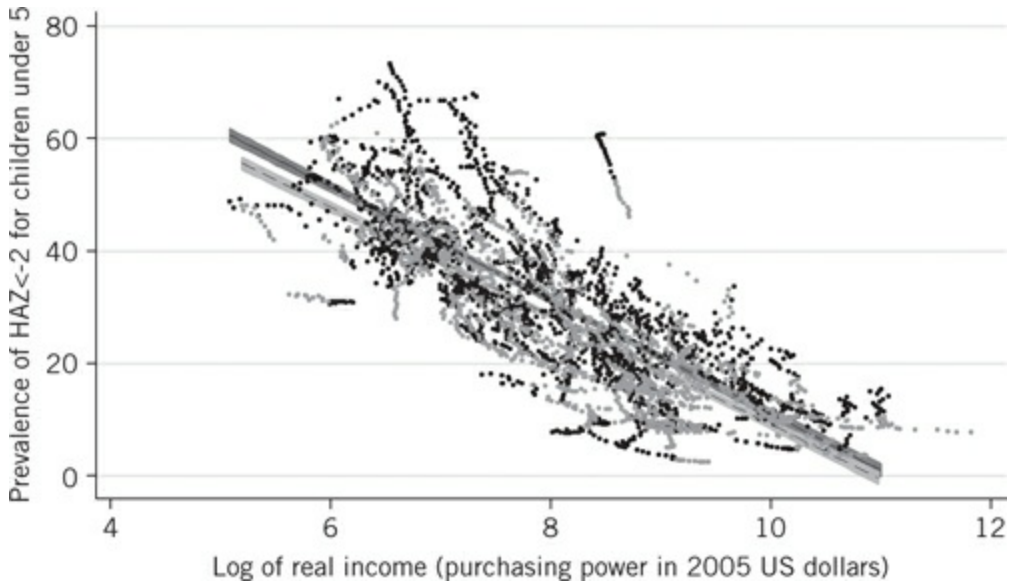

Figure 42-2 Prevalence of stunting and real income, 1985–1999 and 2000–2010 (Ezzati et al estimates, **N** = 3485 from 137 countries).

Note: Data shown are for 1985–1999 (darker shading) and 2000–2010 (lighter shading), with 95% confidence intervals around linear regressions. Sample sizes are *N* = 1978 across 137 countries for 1985–1999 and *N* = 1507 across 137 countries for 2000–2010.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Stunting estimates are courtesy of Prof. Majid Ezzati, as detailed in Stevens et al,[13] downloaded December 30, 2012 from www1.imperial.ac.uk/publichealth/departments/ebs/projects/eresh/majidez

The height-for-age data shown in Figures 42-1 and 42-2 are constructed by the NIMS project, imputing values for the countries and years without survey data.[13] If we limit the picture to actual surveys that are in the WHO's Global Database on Child Growth and Malnutrition,[14] we have a smaller sample size but broader coverage, since we can include a few observations made earlier in time and in industrialized countries. Figures 42-3 and 42-4 use the actual surveys compiled by the WHO to show both stunting and wasting prevalence. Looking first at stunting, Figure 42-3 confirms the result found in Figure 42-2. The regression lines have similar slope and somewhat wider confidence intervals due to a smaller sample size, and yet confirm that there was a significant improvement over time, with less stunting in poor countries for their

income level. Figure 42-4 shows the prevalence of wasting, defined as weight for height z scores below -2. This also has a strong association with income, with the average very poor country having a prevalence rate above 10%, but many countries near the lower bound for this type of malnutrition.

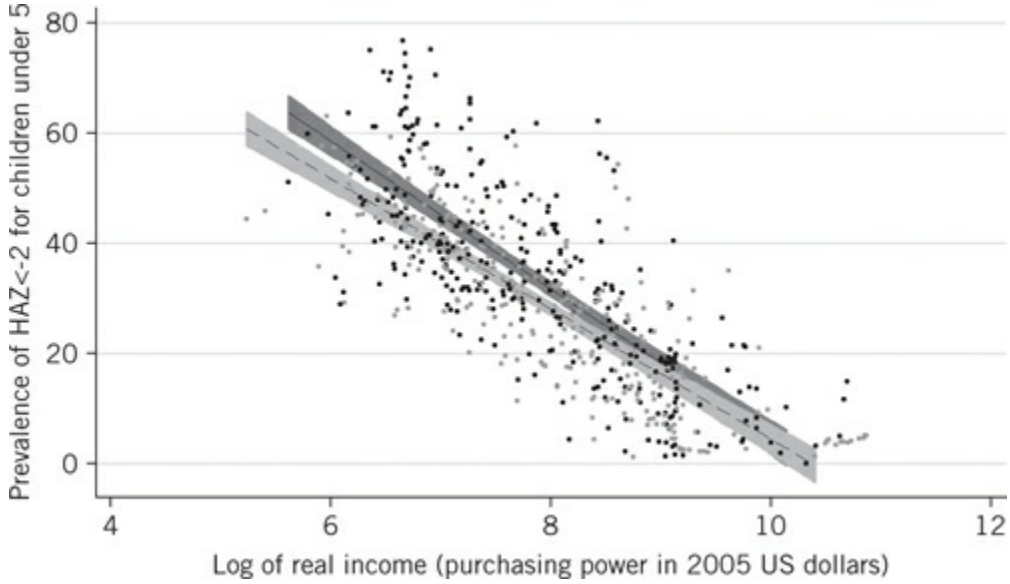

Figure 42-3 Prevalence of stunting and real income, 1966–1999 and 2000–2010 (WHO data, *N* = 608 from 146 countries).

Note: Data shown are for 1966–1999 (darker shading) and 2000–2010 (lighter shading), with 95% confidence intervals around linear regressions. Sample sizes are *N* = 320 across 128 countries for 1966–1999 and *N* = 288 for 127 countries for 2000–2010.

Stunting data are from WHO, Global Database on Child Growth Malnutrition, downloaded December 30, 2012 from World Bank, Health Nutrition and Population Statistics (http://databank.worldbank.org).

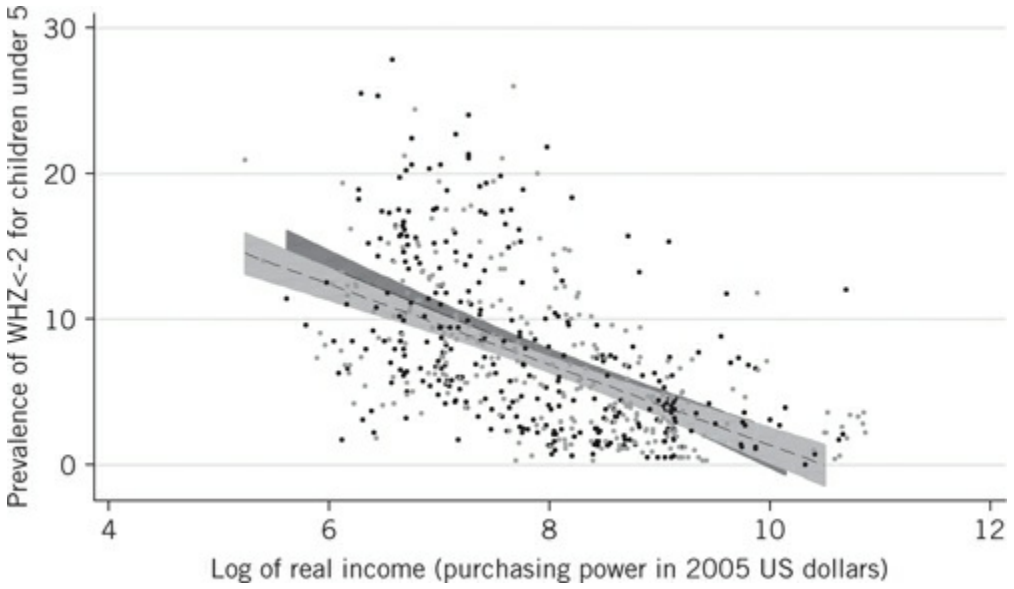

Figure 42-4 Prevalence of wasting and real income, 1966–1999 and 2000–2010 (WHO data, *N* = 601 from 146 countries).

Note: Data shown are for 1966–1999 (darker shading) and 2000–2010 (lighter shading), with 95% confidence intervals around linear regressions. Sample sizes are *N* = 316 across 127 countries for 1966–1999 and *N* = 285 across 126 countries for 2000–2010.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Stunting data are from WHO, Global Database on Child Growth Malnutrition, downloaded December 30, 2012 from World Bank, Health Nutrition and Population Statistics (http://databank.worldbank.org).

Overall, the anthropometric evidence shows a clear positive association between income and child nutritional status, with additional improvement in the 2000s relative to previous decades. This applies both to the prevalence of extreme undernutrition below a z score of -2 as shown in Figures 42-2, 42-3, 42-4, and also to national average child heights as shown in Figure 42-1. These changes in stunting, wasting, and average stature convey different kinds of information. Prevalence rates of extreme conditions are particularly important for targeting interventions to the most needy, whereas changes in means or medians provide more sensitive measures of population-wide changes.[17]

FOOD AVAILABILITY

Diet Quality and Dietary Energy

Child nutrition is not merely a matter of anthropometrics. Dietary patterns are important for many other reasons, including health and activity levels as well as cultural values. Figure 42-5 shows the major changes in food availability associated with per capita income, distinguishing between one aspect of diet quality (on the left axis) and total energy availability (on the right).

The data shown in Figure 42-5 refer to a country's national average family diet. Direct surveys of what children eat have not yet had sufficient precision, over a large enough sample size and range of incomes, to capture the economic-development effects described in this chapter. In fact, even the national-average data shown here are estimates computed by Food and Agriculture Organization (FAO) staff from other observations, using an accounting approach to balance consumption against total production, waste and seed use, international trade, and stock changes. These "Food Balance Sheets" infer the national-average diet from other more readily observed flows in food markets.[18]

The energy availability shown in Figure 42-5 includes all kind of calories. A corresponding measure of food quality could be computed in various dimensions, such as dietary diversity (e.g., the number of distinct types of food consumed on a given day) or food security (e.g., the fraction of time in which households are unable to access needed foods). Here, we introduce the simplest and most direct possible measure of dietary composition, namely the fraction of calories that are derived from animal sources including dairy, eggs, and fish, as well as animal meats.

Figure 42-5 illustrates how many of the world's poorest countries have a nearly vegan diet, while higher income countries get 20% or more of their total calories from animal sources. Various kinds of anthropological and contemporary evidence suggests that availability of these foods at the low levels of consumption observed historically and in today's low-income countries could play a causal role in stature,[19] although that association could also be because of reverse causality, if people who are better nourished and also have higher incomes prefer more animal-sourced foods for taste or other reasons.

DISEASE EXPOSURE AND TREATMENT

Sanitation and Water Supplies, Breast-feeding and

Diarrhea Treatment

Nutritional status depends on the balance between intake and needs, which in turn depends on disease exposure and treatment. Figures 42-6 and 42-7 illustrate some key dimensions of how these factors change during economic development, using datasets assembled by WHO, UNICEF, and the DHS.[14]

Figure 42-6 shows the interrelated issues of access to sanitation and access to improved water sources, compiled by the WHO/UNICEF Joint Monitoring Program (JMP) for Water Supply and Sanitation. For our data, access to sanitation is defined as households using any kind of improved facility such as a protected pit latrine or composting toilet as well as flush toilets, piped sewage and septic tanks, as opposed to open pits, buckets, hanging toilets, or flat land. Access to improved water is defined as any improved source such as protected wells and springs as well as piped water sources, as opposed to open springs, wells, and tanks or surface water. As shown by the two scatter plots and regression lines, in the poorest countries under 20% of the population has access to sanitation, whereas around 50% has access to improved water supplies, and both converge to near 100% at higher income levels. The improvement in sanitation is clearly one of the most dramatic changes in children's nutrition-related environment, being closely associated with diseases discussed elsewhere in this volume including environmental enteropathy.[20]

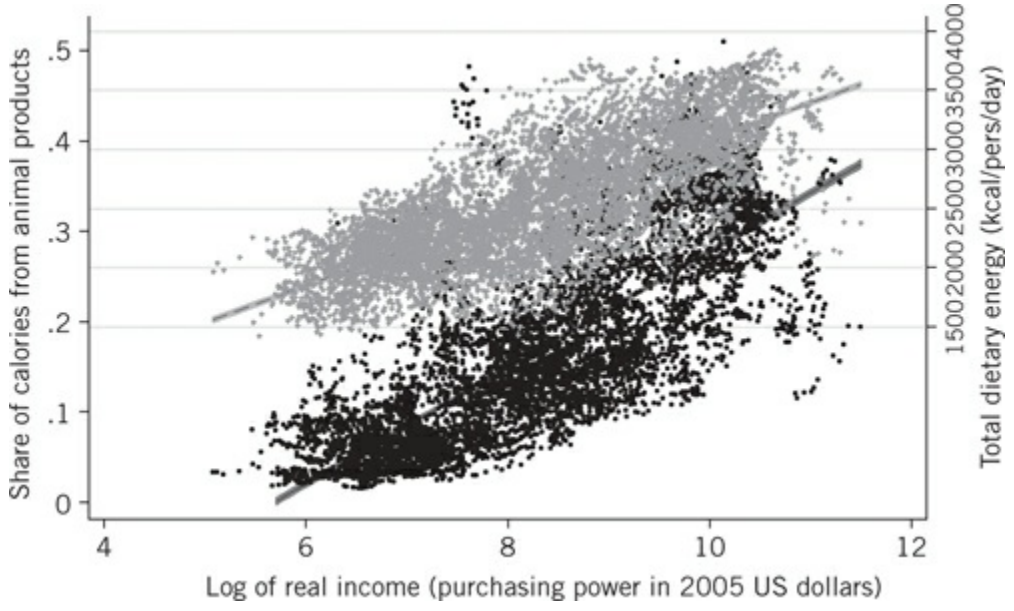

Figure 42-5 Food supply and real income, 1961–2009 (FAO

estimates, *N* = 7031 from 169 countries).

Note: Animal product share is shown in darker shading on the left scale; total energy is shown in lighter shading on the right (higher) scale. Both variables have the same sample size, and linear regression lines with 95% confidence intervals.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Food supply data are Food Balance Sheet estimates, downloaded December 30, 2012 from http://faostat3.fao.org.

Figure 42-7 addresses two other, very different aspects of nutrition-related disease exposure and treatment, namely the fraction of infants under 6 months who are exclusively breast-fed (as opposed to other drinks or solid food), and the fraction of children under 5 for whom diarrhea is treated with oral rehydration and continued feeding (as opposed to suspension of feeding, or other liquids). These appear to have almost no significant correlation with real income across the countries surveyed. The fact that higher income people do not pursue these practices more often does not imply that they are undesirable. Richer people may be able to afford more breast milk substitutes and have less exposure to diarrheal diseases, or may be surveyed differently regarding these practices.

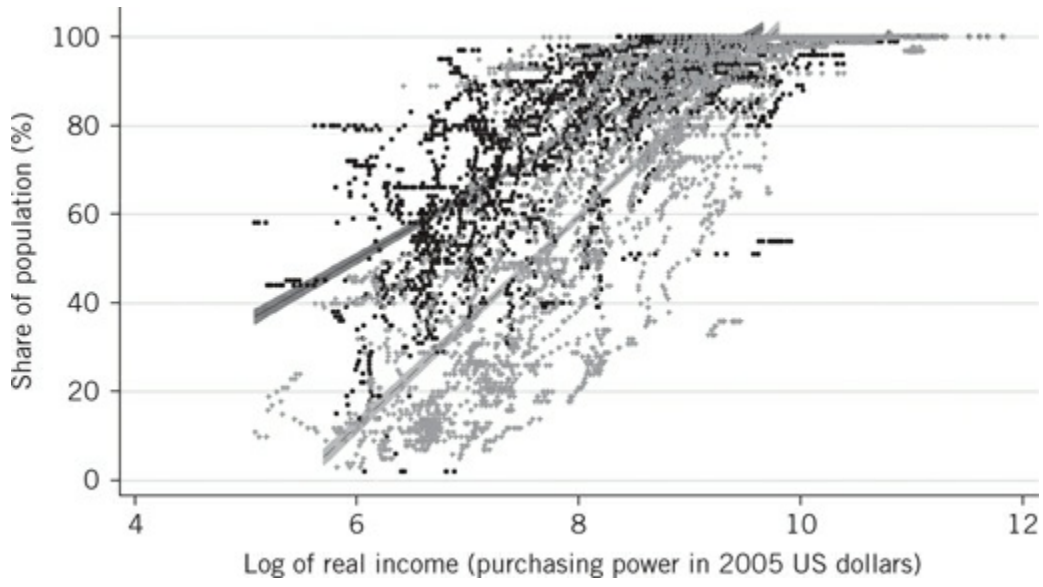

Figure 42-6 Access to sanitation, improved water supplies, and real income, 1990–2010 (WHO and UNICEF data).

Note: Access to improved water (*N* = 3556 from 178 countries) is shown in darker shading; access to sanitation (*N* = 3485 from countries) is shown in lighter shading. Both variables have linear regression lines showing 95% confidence intervals.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Water and sanitation data are from WHO and UNICEF Joint Measurement Program, downloaded December 30, 2012 from World Bank, Health Nutrition and Population Statics (http://databank.worldbank.org).

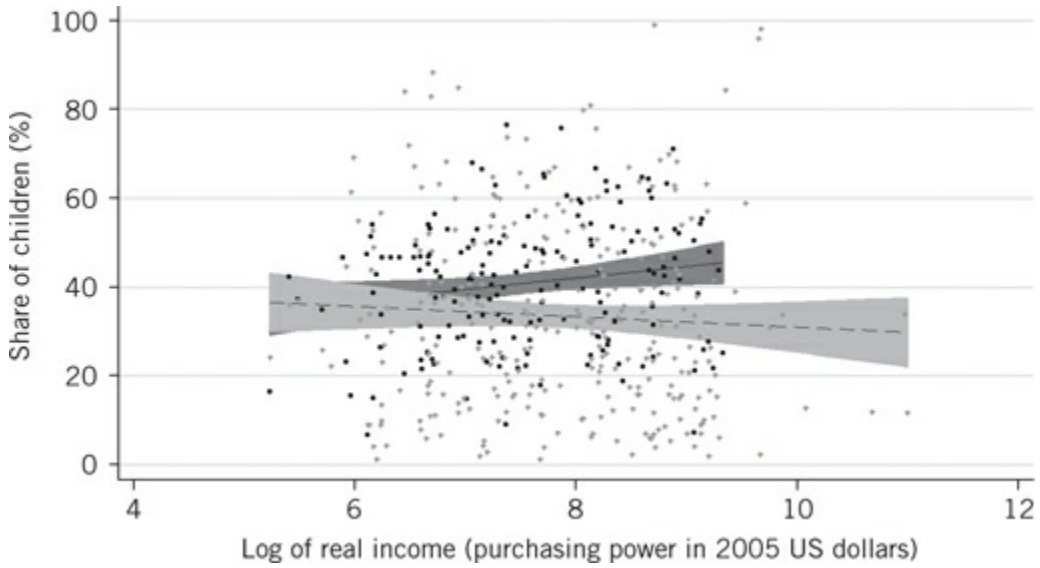

Figure 42-7 Exclusive breast-feeding, diarrhea treatment, and real income, 1990–2010 (UNICEF and DHS data).

Note: Treatment of diarrhea (% of children under 5 receiving oral rehydration and continued feeding) is shown in darker shading, with *N* = 174 from 96 countries. Exclusive breast-feeding (% of children under 6 months) is shown in lighter shading, with *N* = 297 from 134 countries). Both variables have linear regression lines with 95% confidence intervals.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Breast-feeding and diarrhea treatment data are from UNICEF and the Demographic and Health Surveys (DHS) by Macro International, downloaded December 30, 2012 from World Bank, Health Nutrition and Population Statics ((http://databank.worldbank.org).

VACCINATION AND SUPPLEMENTATION

Immunization and Vitamin A Campaigns

The data presented so far are the aggregate result of decentralized decisions taken by individual households. None of the variables shown in Figures 42-1, 42-2, 42-3, 42-4, 42-5, 42-6, 42-7 are directly controlled by government or philanthropic agencies, although these organizations' policies, programs, and interventions do have some influence on individual household behavior. Centralized agencies are relatively more important for the vaccination and supplementation campaigns presented in Figures 42-8 and 42-9, which are typically undertaken on a regional scale by a small number of organizations, to supplement whatever households can do for themselves. Figure 42-8 shows coverage data for vaccination against tuberculosis (BCG) and against diphtheria, pertussis, and tetanus (DPT) among children surveyed between their first and second birthdays, and Figure 42-9 shows coverage of measles vaccination and vitamin A supplementation. Vaccination data are from WHO and UNICEF, whereas vitamin supplementation data are from UNICEF.[14]

The vertical axes in Figures 42-8 and 42-9 show the proportion of children receiving vaccination and supplementation, so the scaling of these scatter plots and regression lines is directly comparable to the population shares shown in Figures 42-6 and 42-7. Visual comparison reveals that vaccination coverage (Figures 42-8 and 42-9) has wider variation at each income level, and less steep increase at higher incomes, than household access to improved sanitation (Figure 42-6). One reason could be that vaccination requires less investment by households themselves, and so can more readily be provided in low-income settings. Vitamin A supplementation coverage (Figure 42-9) is like diarrhea treatment in its relation to economic development, with very wide variation at each income level and less use at higher incomes. Supplementation may be less widely needed at higher incomes, or less likely to attract the support of public and philanthropic agencies.

STRUCTURAL CHANGES AFFECTING CHILD NUTRITION

Agricultural Transformation and Demographic Transition

The figures presented above describe how various dimensions of child nutrition vary with the growth of national income, showing strong trends as well as variation across countries and over time. Two other important influences on child nutrition during economic development involve

structural change within society: the agricultural transformation from farming to other occupations, and the demographic transition from short to long life expectancy. These changes are described in detail elsewhere,[21] and are briefly summarized here in respect to their influence on child nutrition.

Agricultural transformation is a shift in employment and expenditure from food to other enterprises. In the world's poorest societies, most people have no choice but to live in rural areas, relying on natural resources and household labor to obtain food, fuel, and water. If opportunities arise to improve productivity, either within agriculture or in other activities, then people can save and invest, specialize and trade, ultimately moving from into a wide array of services and manufacturing. This transformation occurs within rural areas, and also allows migration to towns and cities, which sustains further economic development. The transformation out of agriculture as incomes rise explains why the poorest people and most malnourished children are typically found in the most agriculturally oriented places, both across and within countries. Because of agricultural transformation, the apparent paradox in economic development that food production is associated with being malnourished can typically be resolved by controlling for real income.

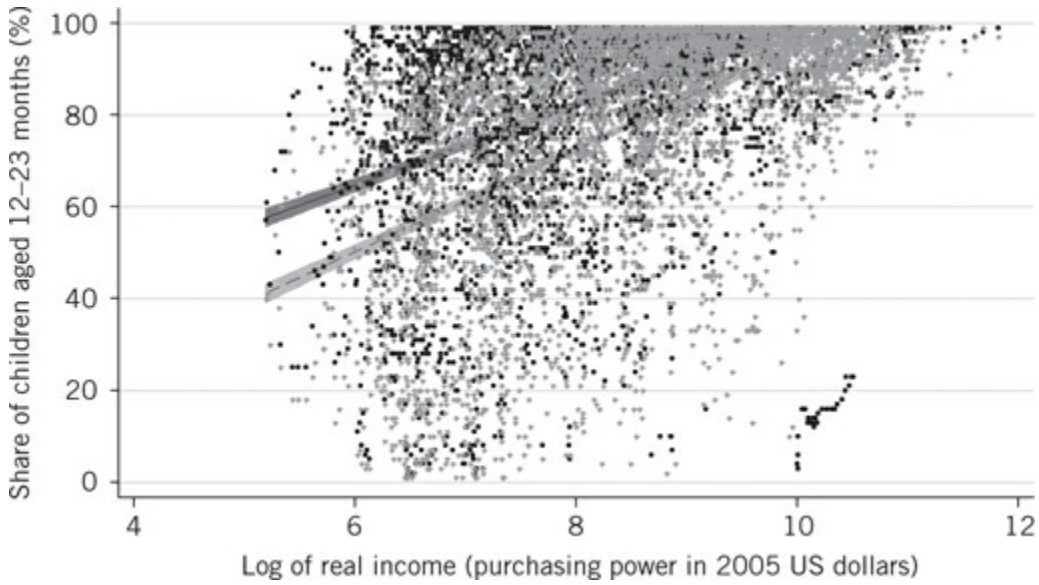

Figure 42-8 BCG and DPT vaccination rates and real income, 1980–2010 (WHO and UNICEF data).

Note: BCG vaccination against diphtheria, pertussis, and tetanus (% of

children, 3 doses) is in lighter shading, with *N* = 5096 from 183 countries. Both variables have linear regression lines with 95% confidence intervals.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Vaccination is from WHO and UNICEF, downloaded December 30, 2012 from World Bank, Health Nutrition and Population Statics ((http://databank.worldbank.org).

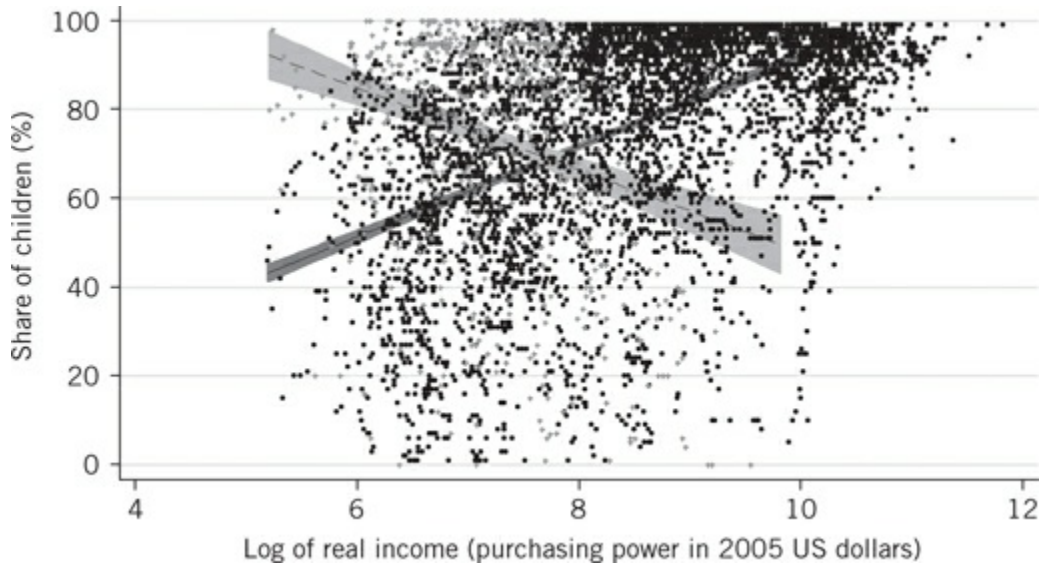

Figure 42-9 Measles vaccination, vitamin A supplementation, and real income, 1980–2010 (WHO and UNCEF data).

Note: Measles vaccination (% of children aged 12–23 mo, single dose) is shown in darker shading, with *N* = 5005 from 183 countries. Vitamin A supplementation (% of children aged 6–59 mo, at least one capsule in the 6 mo before survey) is shown in lighter shading, with *N* = 602 from 86 countries. Both variables have linear regression lines with 95% confidence intervals.

Source: Author's calculation. Income data are from Penn World Table Version 7.1 (November 2012), online at https://pwt.sas.upenn.edu. Vitamin A data begin in 1999 and are from UNICEF. Vaccination data are from WHO and UNICEF, downloaded December 30, 2012 from World Bank, Health Nutrition and Population Statics ((http://databank.worldbank.org).

Demographic transition is another kind of structural change with surprising implications for child nutrition. This familiar shift toward longer life and then also lower fertility almost always starts with lower child

mortality, often associated with an improvement in nutrition. That can lead quickly to a decline in birth rates, particularly if accompanied by opportunities for education, women's employment, and access to contraception, but in the meantime there is a burst of population growth and a demographic burden of more children per household. The rise in child dependency during the demographic transition helps explain why child malnutrition often worsens over time, before it improves. The demographic burden of child care falls disproportionately on young women, until declining fertility rates help the age structure swing back toward more working-age adults per child. The eventual rise in the workforce as a fraction of the population then offers a demographic gift that can fuel rapid economic development, particularly when combined with agricultural transformation and off-farm employment growth.

Demographic transition interacts with agricultural transformation in a way that often makes nutrition improvement harder in low-income countries, and then easier at higher income levels. In poor countries, the nonagricultural sector is initially so small that even very rapid rates of off-farm employment growth cannot absorb all of the increasing number of working-age people. Despite successful year-to-year economic development and rapid urbanization, there will be a rising number of workers who have no choice but to farm, typically with less and less land and other natural resources per worker. That burden of declining land area per farmer in poor countries can be offset only by raising their crop yields, until the size of their country's nonagricultural sector has become large enough its annual growth to absorb each year's increase in the adult workforce.

In summary, these two structural changes associated with economic development impose temporary burdens on child nutrition in low-income countries. By the arithmetic of year-to-year change, they serve to raise the number of children per adult and lower the area of land per farmer in the early stages of structural change, making progress harder before it gets easier. At later stages of economic development, child dependency rates and area per farmer can increase, both of which help the poorest and most malnourished escape more quickly from poverty. The development process may start earlier or later, varies widely in speed and occasionally stalls altogether. But to the extent that economic development proceeds, it is characterized by remarkable similarities that help explain the patterns we see across countries and over time. In that sense, successful societies are alike even as their progress toward that shared destination involves a variety of diverse forces.

CONCLUSIONS

This chapter describes changes in child nutrition that have been associated with economic development over several decades in more than 100 countries. We use data recently assembled from millions of children to compare changes in purchasing power with observed child height, stunting, and wasting, as well as various contributors to nutritional status including food availability and diet quality, sanitation and water supplies, breast-feeding behavior and treatment of childhood diarrhea, vaccination, and vitamin A supplementation. Each aspect of child nutrition has wide variation across countries, but some are closely linked to national income.

The most notable links between nutrition and income are for child height and stunting, both of which improve sharply with economic development especially among the poorest countries. We also find strong links for access to sanitation and diet quality, as measured here by the fraction of calories obtained from animal products. Total food availability, as measured by total calories per person, and access to improved water as well as child vaccination rates are also associated with higher income, although vaccination rates have wide variance across countries at each income level.

Nutrition practices that have almost no correlation with income across the available data are the rates at which children are exclusively breast-fed, or are treated for diarrhea with oral rehydration and continued feeding. Vitamin A supplementation rates are actually lower in more developed countries. These low or negative correlations with income could be because of diminished need for these practices as income rises, or to a lack of public support in richer countries, or perhaps to less frequent observation even when they are practiced.

The links between child nutrition and economic development described in this chapter are accompanied by very large changes within countries, including the agricultural transformation from a focus on food production to more other activities, and the demographic transition from large to small families. Together these impose headwinds against nutrition improvements in low-income countries that help explain the cross-country patterns we see, and make success in those settings all the more remarkable. The extraordinary gains in nutrition associated with economic development are driven by deep social and institutional changes involving gender relations, educational and child care practices as well as medical and nutritional innovations described elsewhere in this volume, all of which offer opportunities for health practitioners and policy officials to achieve even greater improvements in the future.

Global Interventions in Child Health

43

Zulfiqar A. Bhutta, MBBS, FRCP, FRCPCH, FCPS, PhD and Jai K. Das, MD, MBA

The Millennium Summit in the year 2000 led to the formulation of the Millennium Declaration that advocated the provision of basic human rights to all.[1,2] It led to the constitution of Millennium Development Goals (MDGs), which consisted of eight core goals that marked the culmination of years of exhaustive research and consultations, and was approved by 193 United Nations member states.[1,2] Of these goals was the MDG 1; which was to eradicate extreme poverty and hunger and halve, between 1990 and 2015, the proportion of people who suffer from hunger and MDG 4; which was to reduce the under-5 child mortality by two-thirds (baseline of 1990) by the year 2015. Although the role of nutrition in these two MDGs is direct and obvious, nutritional status, dietary intake, food security, and production are integral components of the other MDG's as well (Table 43-1).[3] Malnutrition hinders child education and school performance (MDG 2) and is also risk factors for infection transmission including HIV, malaria, and TB (MDG 6). Gender biases impact women's access to food and health care, consequently leading to maternal undernutrition (MDG 3), hence resulting in compromised maternal health (MDG 5).

Child mortality has been a focus of public health interventions since the early 1980s, and much progress has been made from the early 1990s, when under-5 mortality rates were approximately 12.5 million deaths a year to 2011 when child deaths are approximately 6.9 million.[4] This reduction is notable as the total child population has grown during this time, but has unfortunately not been adequate to achieve the end-points for

2015. The acceleration is slower than desired and now would require a reduction of 13.5% per year as opposed to current global rates of fall of 2.2% per year[5] to be within the reach of MDG 4

In addition, this burden is spread disproportionately across the world and regions of the world with the highest mortality in the Central African states followed by South East Asia, Eastern Mediterranean, and Western Pacific regions, all of which account for around 92%–99% of all child mortality.[6] Unfortunately, most of these deaths are preventable or treatable with existing interventions that are currently available and recommended for universal implementation. About one-third of these deaths in children under 5 years of age are due to underlying undernutrition, which includes stunting, severe wasting, deficiencies of vitamin A and zinc, and suboptimum breast-feeding (BF).[7] An estimated 178 million children under five suffer from stunting, the vast majority in sub-Saharan Africa and South-central Asia (Figures 43-1 and 43-2).[8] Of these, 160 million (90%) live in just 36 countries, representing almost half (46%) of the 348 million children in those countries.[8] An estimated 55 million children are wasted, 19 million of these are severely affected and at high risk of premature death.[8] Altogether, more than 3.5 million mothers and children under five die unnecessarily each year in poor countries due to the underlying cause of undernutrition.[9]

TABLE 43-1 Relationship of Nutrition and MDGs[3]

Goal	Nutrition Effect
Goal 1: Eradicate extreme poverty and hunger.	Malnutrition erodes human capital through irreversible and intergenerational effects on cognitive and physical development.
Goal 2: Achieve universal primary education.	Malnutrition affects the chances that a child will go to school, stay in school, and perform well.
Goal 3: Promote gender equality and empower women.	Anti-female biases in access to food, health, and care resources may result in malnutrition, possibly reducing women's access to assets. Addressing malnutrition empowers women more than men.
Goal 4:	Malnutrition is directly or indirectly associated with most child

Reduce child mortality.	deaths, and it is the main contributor to the burden of disease in the developing world.
Goal 5: Improve maternal health.	Maternal health is compromised by malnutrition, which is associated with most major risk factors for maternal mortality. Maternal stunting and iron and iodine deficiencies particularly pose serious problems.
Goal 6: Combat HIV/AIDS, malaria, and other diseases.	Malnutrition may increase risk of HIV transmission, compromise antiretroviral therapy, and hasten the onset of full-blown AIDS and premature death. It increases the chances of tuberculosis infection, resulting in disease, and it also reduces malarial survival rates.

Evidence-based systematic reviews suggest that substantial improvements in child health can be achieved by making existing, proven, key and affordable interventions available to children who need them the most. Table 43-2 summarizes the maternal directed as well as the child health interventions to address childhood health and undernutrition. These are some of the key steps toward achieving the targets set forth in the MDG 4, especially in the 75 developing countries that have some of the highest child mortality rates as established by United Nations Children's Fund (UNICEF). Knowing the magnitude of the task at hand and the success stories that have lit the way after years of hardwork is extremely important in planning ahead. Any future strategies in reducing excessive child deaths will depend on the availability of local data, and clearly marked evidence of successful and unsuccessful interventions. Our discussion here will give an in-depth account of these interventions along with their effectiveness. We will also discuss the various delivery strategies that can act as catalyst and help ensure that these amenities reach the most needed and at the same time ensuring equity.

WHAT WORKS: INTERVENTIONS TARGETED

TOWARD WOMEN

Poor maternal nutrition contributes to at least 20% of maternal deaths, and increases the probability of other poor pregnancy outcomes including newborn deaths.[10] Prevalence of low body mass index (BMI) among women of reproductive age is an important risk factor for intrauterine growth restriction and low birth weight (LBW), as well as for neonatal mortality. Low BMI is not the only indicator; key indicators include low maternal stature, anemia, and other micronutrient deficiencies. In the following section, we discuss the evidence from maternal-directed nutrition interventions, which impact not only maternal undernutrition but also have subsequent impact on birth outcomes and child health.

Maternal Micronutrient Supplementation

Women in developing countries often consume inadequate levels of micronutrients due to limited intake of animal products, fruits, vegetables, and fortified foods. The resulting micronutrient deficiencies are exacerbated in pregnancy leading to potentially adverse effects on the mother, such as anemia, hypertension, complications of labor, and even death.

Maternal iron deficiency is widespread and globally about 42% pregnant women are anemic. Iron deficiency is the most common cause of anemia and is a risk factor for perinatal complications such as preeclampsia, LBW, prematurity, and perinatal mortality.[11,12] Studies have provided strong evidence to suggest that iron supplementation with or without folic acid results in a significant reduction in the incidence of anemia during pregnancy.[13,14] It has also been reported that iron supplementation during pregnancy can reduce perinatal mortality.[15] A recent review by Imdad et al[16] shows that daily iron supplementation in pregnant women results in a 70% reduction (Relative Risk [RR]: 0.30, 95% Confidence Interval [CI]: 0.19–0.46) in the incidence of anemia at term, a 67% reduction (RR: 0.33, 95% CI: 0.16–0.69) in iron deficiency anemia at term and a 19% reduction (RR: 0.81, 95% CI: 0.68–0.97) in the incidence of LBW.[16] Iron supplementation also has a significant effect on mean birth weight (Mean Difference [MD]: 30.81g, 95% CI: 5.94–55.68). There was however no effect reported on the incidence of preterm or small-for-gestational-age births (SGA).

Another essential micronutrient during pregnancy is calcium, and studies have shown that an inverse relationship exists between calcium intake and the development of hypertension in pregnancy.[17,18]

Preeclamptic women have 2.7 times increased risk of delivering infants with intrauterine growth restriction.[19] Calcium supplementation during pregnancy is associated with a reduction in the risk of gestational hypertensive disorders and has also shown a 52% reduction (RR: 0.48, 95% CI: 0.34–0.67) in the incidence of preeclampsia and 24% reduction (RR: 0.76, 95% CI: 0.60–0.97) in preterm birth accompanied with an increase in birth weight of 85 g.[20] However, there was no effect observed for calcium supplementation on LBW, perinatal mortality, and neonatal mortality.

Animal and human studies have shown that iodine deficiency has multiple adverse effects on growth and development that are collectively termed the iodine deficiency disorders. Iodine deficiency during pregnancy impairs the neurological development of the fetus as thyroid hormone is required for the normal neuronal migration and myelination of the brain during fetal and early postnatal life, and hypothyroxinemia during these critical periods causes irreversible brain damage, with mental retardation and neurological abnormalities.[21] A review by Zimmermann et al[22]

reported that maternal iodine supplementation in moderate-to-severe iodine-deficient areas before or during early pregnancy eliminates new cases of cretinism at 4 years of age by 73% (RR: 0.27, 95% CI: 0.12–0.60), increases birth weight (3.82%–6.30% higher), reduces rates of infant mortality (25%–60% reduction), and increases developmental scores in young children by 10%–20%.[22]

Since multiple-micronutrient (MMN) deficiencies often coexist in low- to middle-income countries, MMN supplementation could be one intervention to limit the potentially adverse newborn health outcomes. A recent Cochrane review[23] shows that MMN supplementation during pregnancy significantly decreased the number of LBW infants by 11% (RR: 0.89, 95% CI: 0.83–0.94) and SGA by 13% (RR: 0.87, 95% CI: 0.81–0.95). MMN supplementation, however, was not associated with lower rates of preterm birth, miscarriage, preeclampsia, maternal mortality, perinatal mortality, still birth, or neonatal mortality.

Maternal Balanced Protein Energy Supplementation

Macronutrient interventions have also been proposed and evaluated in accordance with the maternal needs during pregnancy. Some of the macronutrient interventions include dietary advice to pregnant women, balanced protein energy supplementation, high protein, isocaloric protein supplementation, and prescribing a low-energy diet to pregnant women who are either overweight or who exhibit high weight gain earlier in gestation.[24,25] Balanced protein energy supplementation is defined as nutritional supplementation during pregnancy in which proteins provide less than 25% of the total energy content (ranging from 417 to 1017 kcal). A review by Imdad and Bhuta[26] shows that providing pregnant women with balanced protein energy supplementation results in a significant reduction of 34% (RR: 0.66, 95% CI: 0.49–0.89) in the risk of giving birth to SGA infants and a 38% reduction (RR: 0.62, 95% CI: 0.40–0.98) in stillbirth as well as an increase in birth weight (MD: 73 g, 95% CI: 30–117). These effects were more pronounced in malnourished women when compared to adequately nourished women.

WHAT WORKS: INTERVENTIONS TARGETED TOWARD NEWBORNS/CHILDREN

Factors responsible for childhood undernutrition include lack of early initiation of BF and exclusive breast-feeding (EBF) in the first six months

after birth, lack of sufficient macronutrients and calorie intake, and micronutrient deficiencies (especially vitamin A, iron, iodine, and zinc).

Breast-Feeding Promotion

Breast milk provides numerous immunologic, psychologic, social, economic, and environmental benefits; and is a natural first food and an ideal nutrition for the newborn.[27] BF is therefore recommended as the optimal strategy for feeding newborns and young infants[28–31] (see Chapters 30–32). BF has a significant positive impact on child growth and development and decreases the risk for many acute and chronic diseases,[32–37] including infections such as diarrhea and respiratory tract infections during infancy.[38] EBF rates in infants less than 6 months of age vary from as low as 20% in central and eastern European countries to 44% in South Asia.[39] The reasons for low prevalence of EBF could be the lack of support for BF by social workers and health-care providers, emotional stress in mothers and their perception of not having enough breast milk, and pressure from close relatives to introduce other liquid and solid foods, unsupportive hospital practices that delay early initiation of BF, maternal employment, and lack of commercial advertising.[40] For reasons like these, effective programs of education, counseling, and support are considered necessary to not only promote BF but also to prolong the duration of EBF to up to 6 months of age. BF promotion, therefore, is a global priority with benefits for maternal and child health, especially in low-/middle-income countries where its relevance for child survival is undisputed.[41]

World Health Organization (WHO) recommends EBF the infant for the first six months of life to achieve optimal growth, development, and health.[42] A review by Imdad et al[43] evaluated the effect of BF education and promotion interventions on BF rates and concluded that EBF at 4–6 weeks postpartum improved significantly by 43% with 89% and 20% significant increases in developing and developed countries respectively when compared to no intervention. EBF at six months improved by 137% with a significant six times increase in EBF in developing countries, compared to 1.3-fold increase in developed country studies. The review also showed that prenatal counseling had a significant impact on BF outcomes at 4–6 weeks, although both prenatal and postnatal counseling were important for EBF at six months.

Complementary Feeding

Complementary feeding for infants refers to the timely introduction of safe

and nutritional foods in addition to BF, that is, clean and nutritionally rich additional foods introduced at about 6 months of infant age[35] (see Chapters 36 and 43). These foods are typically provided to children from 6 to 24 months of age.[44] It has been suggested that in addition to disease prevention strategies, complementary feeding interventions targeting this "critical window" are most efficient in reducing malnutrition and promoting adequate growth and development.[45] A review by Imdad et al[46] evaluated the impact of nutrition counseling alone and of provision of complementary foods (with or without nutrition counseling) and showed that these interventions resulted in a significant increases in weight (Weighted Mean Difference [WMD]: 0.30 Standard Deviation [SD], 95 % CI: 0.05–0.54 and WMD: 0.34 SD, 95% CI: 0.11–0.56, respectively) and linear growth (WMD: 0.21 SD, 95 % CI: 0.01–0.41 and 0.26 SD, 95 % CI: 0.08–0.43, respectively).

Micronutrient Supplementation

It is estimated that approximately 600 million preschool and school-aged children are anemic worldwide, and at least half of the cases are due to iron deficiency.[47] A review by De-Regil et al[48] evaluating the impact of iron supplementation in children showed that children receiving intermittent iron supplements have a 49% lower risk of anemia (RR: 0.51, 95% CI: 0.37–0.72) and a 74% lower risk of iron deficiency (RR: 0.24, 95% CI: 0.06–0.91) and have higher hemoglobin (MD: 5.20 g/L, 95% CI: 2.51–7.88) and ferritin concentrations (MD: 14.17 µg/L, 95% CI: 3.53–24.81). Nonsignificant effects were observed for height-for-age and weight-for-age. Evidence on mental development, motor skill development, school performance, and physical capacity was evaluated by very few studies and indicated no clear effect of iron supplementation.

A review by Haider and Bhutta[49] evaluating the effectiveness of neonatal vitamin A supplementation (VAS) showed that for term neonates, infant mortality at six months was reduced significantly by 18% in the vitamin A group compared with the control group (RR: 0.82, 95% CI: 0.68–0.99) and among all infants a 14% significant reduction in the risk of infant mortality at six months was observed (RR: 0.86, 95% CI: 0.77–0.97). A review by Imdad et al[50] on the effectiveness of VAS for preventing morbidity and mortality in children aged 6 months to 5 years showed a 24% reduction in the risk of all-cause mortality (RR: 0.76, 95% CI: 0.69–0.83) and a 28% overall reduction in diarrhea mortality (RR: 0.72, 95% CI: 0.57–0.91). There was no significant effect observed of

VAS on cause-specific mortality due to measles, respiratory disease, and meningitis. VAS also reduced incidence of diarrhea by 15% (RR: 0.85, 95% CI: 0.82–0.87) and measles morbidity by 50% (RR: 0.50, 95% CI: 0.37–0.67); however, there was no significant effect on the incidence of respiratory disease or hospitalizations due to diarrhea or pneumonia.

Zinc is a trace element that serves greater than 300 bodily functions, and deficiency of this micronutrient is said to play a major role in the pathogenesis of diarrhea.[51] Current evidence collected over the last decade suggests that zinc can potentially confer a protective effect to two particular systems, which are the gastrointestinal and respiratory systems.[52,53] Adequate zinc is a prerequisite to maintaining normal development, growth, and also contributes substantially to maintaining the immune system, therefore, its importance cannot be stressed enough in children under the age of 5, which suffer a large burden of diarrheal illnesses across the globe[54,55] (see Chapter 62). Current evidence suggests that the provision of zinc on a weekly basis for a period of one year among young children in developing countries can help lower mortality levels, by either reducing the severity of diarrhea, its duration, or by way of prevention.[51,56–58] A review by Imdad et al[59] of zinc supplementation showed that a dose of 10 mg zinc/d for duration of 24 weeks could lead to a net a gain of 0.37 (±0.25) cm in zinc-supplemented group compared to placebo. A separate review by Yakoob et al[60] evaluated 18 studies from developing countries showed that zinc supplementation decreased the incidence of diarrhea by 13% (RR: 0.87; 95% CI: 0.81, 0.94) and reduced pneumonia morbidity by 19% (RR: 0.81; 95% CI: 0.73, 0.90) but had nonsignificant effects on mortality. The impact of therapeutic zinc supplementation for the management of diarrhea was evaluated by Walker et al.[61] The zinc dose included was 10–40 mg/d, which aligns with the WHO recommendations of 20 mg/d (for children aged 6–59 months) and 10 mg/d (for those 1–5 months). The review concluded that zinc supplementation reduced all-cause mortality by 46% and diarrhea-related hospitalization by 23%, while there were nonsignificant impacts on diarrhea-specific mortality and diarrhea prevalence. In another review, therapeutic zinc supplementation as an adjunct in the treatment of diarrhea has shown to reduce the duration of acute diarrhea by 0.5 days and that of persistent diarrhea by 0.68 days.[62] These analyses support the inclusion of preventive zinc supplementation in public health programs to improve child health and survival.

Providing multiple micronutrients via supplements, powders, or

fortified ready-to-use foods is increasingly becoming a strategy for simultaneously addressing multiple nutrient deficiencies in developing countries. A review[63] on MMN supplementation with three or more micronutrients for children showed small effect sizes of (MD: 0.13, 95% CI: 0.06, 0.21) for length/height and (MD: 0.14, 95% CI: 0.03, 0.25) for weight, and there was limited evidence for an impact on outcomes such as morbidity and cognitive function. A review concluded that home fortification with micronutrient powder reduced anemia by 31% (RR: 0.69, 95% CI: 0.60–0.78) and iron deficiency by 51% (RR: 0.49, 95% CI: 0.35–0.67) in infants and young children, however, no effect was observed on growth. The micronutrient powders containing multiple nutrients are well accepted but adherence is variable and in some cases comparable to that achieved in infants and young children receiving standard iron supplements as drops or syrups.

WHAT WORKS: INTERVENTIONS FOR DISEASE PREVENTION

Recurrent infectious illnesses contribute to the undernutrition burden, and strategies devised at the prevention and treatment of recurrent infections can help reduce this burden. Among these include the water, sanitation, and hygiene (WASH) interventions, as well as interventions, such as vaccines, for the prevention and treatment of diarrhea and malaria.

There are serious adverse health consequences of poor access to WASH, particularly in children, including diarrhea, respiratory illness, trachoma, and death. A review drawing upon three systematic reviews focused on the effect of hand washing with soap on diarrhea, of water quality improvement and of excreta disposal. It concluded that hand washing with soap significantly reduces diarrhea morbidity by 47% (RR: 0.53, 95%CI: 0.37–0.76) though it depends on access to water. The effect of water treatment on diarrhea morbidity also appears similarly large with a 42% reduction (RR: 0.58, 95% CI: 0.46–0.72). There is very little rigorous evidence for the health benefit of sanitation.

WHO recommends that all school children should be treated at regular intervals with deworming drugs in helminthic prevalent areas. A recent Cochrane review[64] showed that single dose deworming had a nonsignificant effect on hemoglobin while multiple doses at one year follow up, also had a nonsignificant effect on weight, hemoglobin, cognition, and school attendance while the results were same for greater

than one year follow-up. But treating children after screening for worms showed that a single dose of deworming drugs may increase weight (MD: 0.58 kg, 95% CI: 0.40–0.76) and hemoglobin (MD: 0.37 g/dL, 95% CI: 0.1–0.64), while evidence on cognition was inconclusive. Administration of a single dose of antihelminthics in the second trimester of pregnancy also failed to show a statistically significant impact on maternal anemia (RR: 0.88, 95% CI: 0.69–1.13). A single dose of antihelminthics in the second trimester of pregnancy was not associated with an impact on LBW, preterm births, and perinatal mortality.

Effective interventions to prevent malaria morbidity and mortality include insecticide-treated mosquito nets (ITNs), indoor residual spraying, and intermittent preventive therapy (IPTc). A Cochrane review[65] concluded that antimalarials, when given to prevent malaria in pregnant women, increased mean birth weight significantly (MD: 126.70 g, 95% CI: 88.64–164.75 g) and reduced the incidence of LBW by 43% and severe antenatal anemia by 38%.[65] Another Cochrane review[66] evaluated the impact of ITNs with no nets and concluded that ITNs in pregnancy reduced LBW by 23% (RR: 0.77, 95% CI: 0.61–0.98) and fetal loss in the first to fourth pregnancy by 33% (RR: 0.67, 95% CI: 0.47–0.97), while effects were nonsignificant for anemia.

TABLE 43-3 Median National Coverage of Countdown Intervention (%) Based on Most Recent Measurement Since 2006, With Number of Countries Reporting and Range[68,69]

Countdown Indicator	No. of Countries With Data	Median Coverage (%)	Range (%)
Prepregnancy			
Demand for family planning satisfied	46	56	17–97
Pregnancy

[a]For the malaria indicators, the number of countries is based on those countries with 75% or more of the population at risk of *Plasmodium falciparum* transmission with an estimate during the time period 2006–2010.

Source: Adapted from Bhutta et al[68] and Countdown to 2015.[69]

Evidence-Based Intervention's Coverage Trends

Existing proven strategies to improve child health include promotion of BF, dietary supplementation of micronutrients, prevention of protein-energy malnutrition as far as possible, and improvement in the standard of preparation and hygiene of available weaning foods.[67] The median national coverage of these interventions in countdown countries since

2006 is summarized in Table 43-3.[68,69] All four vaccines (measles, DTP3, HiB3, neonatal tetanus protection) and vitamin A (two doses) have reached a median coverage level of 80% or more in the Countdown countries with available data. In most Countdown countries, vaccines and vitamin A are provided in fixed health facilities as well as during campaigns such as national child health days (CHDs) when outreach teams are able to reach high proportions of the population.

The current intervention coverage trends show that substantial progress is still needed. The median coverage levels for several interventions hover at or below 50% including interventions related to early initiation and EBF for at least six months, case management of childhood illnesses, and demand for family planning satisfied.[68,69] In absolute terms, the slowest absolute gains have been observed for oral rehydration solution (ORS) use and early initiation of BF, both with 4%. However, absolute gains need to be interpreted with caution because increases are harder to achieve if baseline levels are already high.[68,69]

Table 43-4 shows progress in intervention coverage from 2000–2005 to 2006–2011.[68,69] Coverages for the interventions requiring strong health systems (skilled attendant at birth, ORS) or those requiring behavior change (BF, care seeking for pneumonia) appear to be stalled between 30% and 50%, suggesting that what we have been doing for these interventions over the past decade is not working and needs to be reexamined, to find more effective ways of reaching the women and children who need to receive them.

WHAT CAN WORK: DELIVERY STRATEGIES AND PLATFORMS

Although individual interventions such as EBF, micronutrient supplementation, deworming, and malaria treatment have shown to be effective, an integrated approach is needed to achieve optimal results. The coverage of various proven interventions discussed above is below the mark and various delivery strategies have been undertaken to increase the uptake of these interventions. The measures discussed below not only ensure effective delivery but also ensure equity.

Integrated Management of Childhood Illnesses

In the mid-1990s, the WHO, in collaboration with UNICEF and other agencies, developed a strategy known as the Integrated Management of

Childhood Illness (IMCI). It includes both curative and preventive interventions targeted at improving the health practices at health facilities, at home, and in the community. Evaluations of IMCI in Uganda, Tanzania, Bangladesh, Brazil, Peru, South Africa, China, Armenia, Nigeria, and Morocco have shown various benefits in health service quality, mortality reduction, and health-care cost savings.[70] In Bangladesh, in the last two years of the study, the mortality rate was 13.4% (95% CI: 14.2–34.3) lower in IMCI than in comparison areas, corresponding to 4.2 fewer deaths per 1000 live births (95% CI:4.1–12.4, *P* = 0.30). It also reported an increase in exclusively breast-fed children (76% vs. 65%, difference of differences 10.1%, 95% CI: 2.65–17.62), and the prevalence of stunting in children aged 24–59 months decreased more rapidly than in comparison areas.[71]

TABLE 43-4 Trends in Countdown Indicators, Countries With Data From at Least Two Surveys; 2000–2005 and 2006–2011[68,69]

Countdown Indicator	No. of Countries With Data	Median Coverage, 2000–2005 (%)	Range, 2000–2005 (%)	Median Coverage, 2006–2011 (%)	Range, 2006–2010 (%)	Ch in Pe Po
Antenatal care (at least one visit)	61	76	27–98	88	34–100	
Skilled attendant at birth	61	49	6–99	57	10–100

ITN[b]	26	2	0–23	37	3–64	

[a]The immunization data, measles and DTP3, are based on the interagency estimates from 2002 to 200 average reference years for calculating trends for the nonvaccine indicators included in Table 43-3.

[b]For the malaria indicators, analyses are restricted to countries with 75% or more of the population at ris *falciparum* transmission, and with trend data available.

Source: Adapted from Bhutta et al[68] and Countdown to 2015.[69]

School Feeding Programs

Many countries have introduced school feeding programs designed to improve attendance, achievement, growth, and other health outcomes. A Cochrane review[72] on the effectiveness of school feeding programs reported an average of 0.39 kg (95% CI: 0.11–0.67) gain in weight over an average of 19 months and 0.71 kg (95% CI: 0.48–0.95) over 11.3 months. For height, results were mixed and height gain was greater for younger children. Attendance also increased by 4–6 days a year. In short-term studies, small improvements in some cognitive tasks were also found. School meals may have some small benefits for disadvantaged children, while further well-designed studies on the effectiveness of school meals should be undertaken and results reported according to socioeconomic status.

Child Health Days

CHDs have been introduced in many settings in response to the declining coverage of many essential child survival interventions as a result of weakening health systems. However, formal large-scale evaluations considering both positive and negative effects on health-related outcomes are required. A review of CHDs from 1999 to 2009[73] presents a broad picture of the scale-up of CHDs for the delivery of key child health and nutrition interventions. It confirms that CHDs have become a popular mode of delivery for a wide range of services. The authors suggest that CHDs are generally more effective than stand-alone campaigns, but if the number of interventions exceeds four, they may have a negative impact on coverage. Still CHDs may not be reaching those who need it most, so countries need to prioritize a specific number of interventions to be delivered through CHDs and also determine how to integrate this routine health care to impart effective and equitable delivery of services.

Community Platforms

Employing local semiskilled labor, and giving them the necessary training and resources to identify and treat certain common conditions, will increase the outreach of preventive and therapeutic strategies, as well as increase equity.[74–76] The concept of community case management, where community health workers have been employed to impart cost-effective treatment for conditions such as diarrhea and pneumonia, have also been

initiated. This is a strategy that has the potential to accelerate the pace toward achieving the goals set for MDG 4.[77]

A review on the effectiveness of community-based intervention packages in reducing maternal and neonatal morbidity and mortality and improving neonatal outcomes reported significant reductions in maternal morbidity (RR: 0.75, 95% CI: 0.61–0.92), neonatal mortality (RR: 0.76, 95% CI: 0.68–0.84), stillbirths (RR: 0.84, 95% CI: 0.74–0.97), and perinatal mortality (RR: 0.80, 95% CI: 0.71–0.91).[33] These interventions also increased referrals to health facility for pregnancy-related complication by 40% (RR: 1.40, 95% CI: 1.19–1.65), and improved the rates of early BF by 94% (RR: 1.94, 95% CI: 1.56–2.42).

CONTEXTUAL FACTORS: FOOD INSECURITY AND INEQUITIES

Despite the above-mentioned existing proven interventions, progress in improving child health and reducing undernutrition has been painfully slow. Though many countries are on track in reducing income poverty (MDG 1a), less than a quarter of developing countries are on track for achieving the goal of halving undernutrition (MDG 1c). The global burden of undernutrition remains high with little evidence of change in many countries despite economic growth. Millions of people are faced with starvation and malnutrition. The State of Food Insecurity in the World 2012 estimates that about 870 million people have been undernourished (in terms of dietary energy supply) in the period 2010–2012.[78] The vast majority of these, 852 million, live in developing countries, where the prevalence of undernourishment is around 14.9% of the population.[78] Food security is a complex issue resulting from a mix of climate change, rural poverty, inadequate stress on agricultural growth, urban development, population growth, oil price shifts, general inflationary trends, political influences, power balances, internal and external displacement of people, poor governance, and inequitable distribution of wealth and other resources. Paradoxically, there’s enough food in the world to feed everyone. Despite global food sufficiency, its inequitable distribution within countries and within households affects individuals at every level with too much for some and too little for the others. Women and children are among the highly affected population groups due to the discriminatory unequal and inequitable power relationships and practices.

WAY FORWARD

With these data in mind, it is important to note that currently global child mortality stands at 6.9 million deaths per year and to achieve the aims set forth for the MDG-2015, there is still much progress to achieve. However, to realize those aims, current preventive practices need to be formulated into appropriate unified guidelines. Given the wide disparities in the coverage of existing interventions, the challenge is to implement appropriately packaged interventions targeting the ones in need. This would require addressing the various contextual factors simultaneously including poverty, agricultural growth, education, and political commitment. Emerging data from community intervention trials now provide evidence that such efforts are both feasible and can lead to alleviation of childhood undernutrition. The latest Countdown Report[69] suggests that countries should implement national health plans that emphasize service integration, strengthen health information systems, increase domestic funding allocations on health, improve the health of the workforce, and identify gaps and inequities to increase coverage of essential health interventions across the full continuum of care, especially for the poor.

Pediatric HIV Infection

44

Colleen Hadigan, MD, MPH and Anna Coutsoudis, PhD

There are a number of nutritional challenges that clinicians face in the care of children infected with human immunodeficiency virus (HIV). Important interactions between the immune system and nutritional status, which are discussed in this and other chapters, have led to the recognition that treatment of nutritional problems can play a critical role in the health and well-being of HIV-infected children. Careful attention to the nutritional needs of children with HIV can help optimize growth, and more importantly may improve clinical outcomes including hospitalization rates and survival. This chapter will provide current background information on pediatric HIV infection and the associations between nutrition and HIV. Focus is also given to nutritional management in resource-limited settings where the HIV epidemic continues to affect large numbers of children. Furthermore, the growth patterns of HIV-infected children, metabolic complications of HIV and its therapies, and current nutritional diagnostic and therapeutic interventions are presented. It is hoped that this chapter provides practical advice to clinicians caring for HIV-infected children as well as stimulates much needed scientific research in this area.

HIV AND THE PEDIATRIC HIV/AIDS EPIDEMIC

HIV is an RNA virus that belongs to the lentivirus family and was first isolated in 1983. HIV is a virus with a particular tropism for the CD4 surface antigen of cells, and the binding of HIV to the CD4 receptor initiates the viral life cycle, which includes the replication of the virus within the host cell. Human T lymphocytes and monocyte or macrophages are the primary cells that are infected with HIV. The net biological effect of HIV infection is impairment of the immune system through the

progressive decline in CD4-positive T lymphocytes, leaving those infected with HIV susceptible to opportunistic and recurrent bacterial infections. Treatment of HIV with antiretroviral (ARV) medications suppresses HIV viral replication and permits reconstitution of the immune system with a compensatory rise in the CD4-positive T cells. While there are significant clinical and immune benefits of therapy, it is important to note, however, that even among treated patients with undetectable HIV viral RNA in the blood, virtually all patients develop detectable virus after withdrawal of therapy.

There has been dramatic progress made over the past two decades regarding the prevention, detection, diagnosis, and treatment of HIV infection, but HIV continues to be a global epidemic. The World Health Organization and the UNAIDS report on the global AIDS Epidemic estimated that 34 million people worldwide were living with HIV/AIDS in 2011.[1] Efforts to expand access to ARV therapy (ART) and to provide prenatal counseling, testing, and therapy are ongoing with impressive improvements seen in regions of the world with high HIV prevalence. The UNAIDS 2011 report documented encouraging global declines in the number of cases of mother-to-child transmission and of deaths in persons under age 15 years attributable to HIV. In high-income countries such as the United States, new infections among children dropped by 93% between 1992 and 2005, and now similar progress is being detected in lower income regions. Between 2002 and 2010, new infections among children declined approximately 30% with the majority (86%) of averted infections occurring in the region of sub-Saharan Africa. Nonetheless, as of 2011, over 2 million children were living with HIV infection. The greatest burden of pediatric HIV infection remains concentrated in regions of the world where endemic problems of protracted diarrhea and severe malnutrition often co-exist, emphasizing the importance of nutrition in the approach and management of HIV infection in children.

NUTRITION AND IMMUNITY

Nutritional status and immunity have long been linked, and malnutrition is the most common cause of immunodeficiency worldwide. Long before HIV was described, opportunistic infections such as *Pneumocystis carinii* pneumonia were described in otherwise healthy but malnourished individuals in developing nations.[2] This association led investigators to conclude that nutrition alone can impact on the immunologic response of an individual. In malnourished children, for example, there is a profound

involution of lymphoid tissues. In young infants and children, protein-energy malnutrition increases the risk of death several fold by increasing susceptibility to infection.[3] Historically, mortality rates in many countries increase from 0.5% in children whose weight-for-height percent of standard is greater than 80%, to a mortality rate of 18% in children whose weight-for-height percent of standard is less than 60%.[4]

Biochemically, protein-energy malnutrition leads to changes in several aspects of the immune system that are similar to the immunologic changes in HIV infection. Cell-mediated immunity, antimicrobial function of phagocytes, complement systems, secretory antibodies, and antibody affinity are consistently impaired in patients with significant malnutrition. Additionally, deficiencies of micronutrients, especially zinc and vitamin A, as well as many others, may also have deleterious effects on the immune system. Other aspects of immunity that are altered by protein-energy malnutrition include impaired chemotaxis of neutrophils, decreased lysozyme levels in serum and secretions, and decreased interferon production in antibody response to T-cell-dependent antigens. A child with protein-energy malnutrition may also have impaired mucosal immunity with lowered concentrations of secretory IgA in saliva, nasopharynx, and tears compared with well-nourished children.

Because many of the immunologic changes in malnutrition are similar to those found in children infected with HIV, malnutrition has been identified as a cofactor of immune dysfunction by influencing both susceptibility to HIV infection and progression of the disease. Therefore, improving the nutritional status of an HIV-infected child may improve the function of an already compromised immune system and subsequently prolong health and survival.

WASTING IN HIV-INFECTED CHILDREN: PATHOGENESIS

Globally, severe weight loss, growth failure, and wasting remain a central component of HIV infection in children, even in the era of more widely accessible ART. The pathogenesis of malnutrition or the wasting syndrome in pediatric HIV disease is most likely multifactorial. Identified risk factors include fever, diarrhea, acute and opportunistic infections, anorexia, as well as social factors such as ill parents or caregivers, food insecurity and lack of clean water. For example, in a recent cross-sectional study of undernutrition in Dar es Salaam Tanzania, Sunguya, and

colleagues[5] showed that 13.6% of HIV-infected children treated with ART met criteria for wasting (weight-for-height Z-score < −2 SD). Important factors associated with wasting in this study were the presence of diarrhea and low feeding frequency. The four key mechanisms for weight loss and wasting in HIV infection, which are considered in this section, are inadequate oral intake, impaired gastrointestinal absorption, abnormal or increased energy utilization, and psychosocial influences. In many cases, however, several factors may be operating simultaneously.

Energy Intake

A variety of potential factors may lead to abnormal energy intake, as outlined in Table 44-1. For example, inflammation and ulceration of the upper gastrointestinal tract can lead to anorexia owing to odynophagia, dysphagia, or abdominal pain associated with eating. These lesions may be due to infectious agents such as *Candida albicans*, cytomegalovirus, or herpes simplex virus, as well as acid-related injury, all of which may cause inflammation and pain with swallowing or after eating, and thus diminished energy intake.

Pancreatic and biliary tract diseases can also cause vomiting and abdominal pain in HIV-infected children leading to poor oral intake. Pancreatic dysfunction has been linked to medications used in HIV (e.g., nucleotide reverse transcriptase inhibitors, protease inhibitors, sulfonamides) and opportunistic infections (e.g., cytomegalovirus and mycobacterial disease). Biliary tract disease, such as sclerosing cholangitis and papillary stenosis, while less common, has been associated with *Cryptosporidium*, cytomegalovirus and *Microsporidia* infection. Elevations in circulating cytokines such as interleukin-6 and tumor necrosis factor (TNF)-α in association with HIV infection and other opportunistic infections are believed to contribute directly to anorexia. Lettow and colleagues found, for example, that interleukin-6 levels and HIV viral burden were closely associated with severe wasting and loss of appetite among a cohort of HIV-infected adult patients with pulmonary tuberculosis in Malawi.[6] Side effects of ART may also contribute to decreased energy intake. There are currently more than 25 agents approved by the US Food and Drug Administration for the treatment of HIV and many of these as well as other medications frequently used in HIV-infected children may result in gastric irritation, vomiting, and nausea (See Table 44-2).

TABLE 44-1 Causes of Malnutrition in HIV-infected Children

Decreased Nutrient Intake	Mechanism
Peptic disease	Pain
Opportunistic infections of upper gastrointestinal tract (Candida, CMV, HSV)	Pain, dysphagia
Pancreatic/hepatobiliary disease	Pain
Encephalopathy	Uncoordinated swallow
Aphthous ulcers	Pain
Primary anorexia	Nausea, CNS, cytokines
Gastrointestinal Malabsorption	
Mucosal disease	
Infectious	Bacterial, parasitic, viral
Inflammatory	HIV enteropathy
Disaccharidase deficiency	Infectious, inflammatory
Protein-losing enteropathy	Infectious, inflammatory
Fat malabsorption	Infectious, inflammatory
Hepatobiliary	
Sclerosing cholangitis	Infectious
Chronic pancreatitis	Infectious, Drug-induced
Cirrhosis	HBV, HCV
Increased nutritional requirements or tissue catabolism	
Protein wasting	Fever, infections, sepsis
Hypermetabolism	Neoplasms (Kaposi's
Futile metabolic cycling	sarcoma, lymphoma)
	Medications
	Release of catabolic factors
	(cytokines, tumor necrosis factor)
Psychosocial Factors	
Poverty	
Illness in biological family members	
Limited access to health care	
Substance abuse	

CMV, cytomegalovirus; CNS, central nervous system; HBV, hepatitis B virus; HCV, hepatitis C virus; HSV, herpes simplex virus.

There are increasing data suggesting decreased energy intake among HIV-infected children who have more symptomatic infection and/or growth failure. For example, Arpadi and colleagues[7] found, in the absence of active secondary infections or other illnesses, HIV-infected children with growth failure had significantly lower mean energy intake (77% of the RDA) compared with HIV-infected children without growth failure (103% of the RDA for mean energy intake). In this study, when energy balance was assessed as the difference between energy intake and total energy expenditure, HIV-infected children with growth failure had a 674 kJ/d deficit whereas those without growth failure had a surplus intake of 1448 kJ/d. Therefore, while energy intake below the RDA is not common in HIV-infected children during stable periods of disease, inadequate energy intake occurs during symptomatic periods of disease and may contribute to growth failure.

Gastrointestinal Absorption

Adequate nutrient absorption is essential to maintain growth and nutrition in infants and children. HIV-infected patients are at risk for developing malabsorptive disorders, which can potentially impact on their growth and nutritional status. Reasons for gastrointestinal malabsorption in HIV-infected children include infections of the gastrointestinal tract and/or direct and indirect effects of HIV on the intestinal epithelial cell. Infections that are known to affect the small bowel and that may promote malabsorption of nutrients include *Cryptosporidium*, *Isospora belli*, *Microsporidia*, *Mycobacterium avium-intracellulare* complex (MAC), *Giardia lamblia*, and enteric viruses. These pathogens can injure the intestinal epithelial cell where critical digestive enzymes are present to digest essential nutrients. Enteric infections may also decrease bowel transit time, thus shortening nutrient contact with the epithelial cell and causing malabsorption. Malnutrition alone can cause villous blunting and secondary malabsorption of nutrients, which would further impact on nutritional status. Malabsorption has also been linked to an “HIV enteropathy” where the villi are blunted with a hypercellular lamina propria and absence of a detectable enteric pathogen.[8] There is evidence of enterocyte cell death or apoptosis. In addition, in vitro studies of enterocytes show that HIV exposure and/or exposure to HIV gp120 may evoke disruption of microtubules, and tight junctions as well as impaired ion flux, suggesting a pathophysiologic mechanism for HIV enteropathy and malabsorption.[9,10] The fact that many HIV-infected children live in

areas of the world with a high prevalence of tropical or environmental enteropathy make studies of this entity difficult.

In the pre-HAART era, a few studies provided evidence of malabsorption in HIV-infected children.[11,12] For example, in one Italian study,[11] intestinal function of 47 symptomatically infected children was compared with 50 uninfected children with diarrhea and 48 healthy children. Intestinal absorption was measured using the steatocrit method to determine fat absorption, fecal concentration of α-1-antitrypsin as a measure of protein absorption, and d-xylose absorption. Fecal fat loss was detected in 30%, carbohydrate malabsorption in 32%, and protein loss in 17% of HIV-infected children. Investigators found intestinal dysfunction was not associated with diarrhea, poor growth, enteric infections, or degree of immune dysfunction, but was significantly different than healthy control children. In a similar series, Sentongo et al.[12] identified fat malabsorption in 39% of 44 HIV-infected children, but no patient had exocrine pancreatic insufficiency and there was no relationship between steatorrhea, growth, HIV viral load or CD4 count. Thus, although malabsorption is fairly common, it cannot completely account for the gastrointestinal symptoms or malnutrition in HIV-infected children.

TABLE 44-2 Common Gastrointestinal Side Effects Associated with Medications Used in HIV Care

Side Effects	Medications
Nausea	NRTI: abacavir, didanosine, emtricitabine, lamivudine, stavudine, zidovudine
	NNRTI: efavirenz, nevirapine
	PI: atazanavir, darunavir, indinavir, nelfinavir, ritonavir, saquinavir, tipranavir
	Integrase Inhibitor: raltegravir, elvitegravir
	Antiviral: acyclovir, ganciclovir
	Antibacterial: macrolides, sulfonamides, rifampin
	Antiparasitic: pentamidine, atovaquone
Abdominal pain	NRTI: abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine
	NNRTI: nevirapine
	PI: amprenavir, atazanavir, darunavir, indinavir, nelfinavir, ritonavir, saquinavir

	Integrase Inhibitor: raltegravir, elvitegravir
	Antibacterial: macrolides, sulfonamides, ciprofloxacin, rifampin
	Antiparasitic: pentamadine
Vomiting	NRTI: abacavir, didanosine, emtricitabine, lamivudine, stavudine, zidovudine
	NNRTI: efavirenz
	PI: amprenavir, atazanavir, indinavir, nelfinavir, ritonavir
	Integrase Inhibitor: raltegravir, elvitegravir
	Antiviral: ganciclovir
	Antibacterial: macrolides, sulfonamides, ciprofloxacin, rifampin
	Antiparasitic: pentamadine, atovaquone
Diarrhea	NRTI: emtricitabine, lamivudine
	PI: amprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, saquinavir, tipranavir
	Integrase Inhibitor: elvitegravir
	Antibacterial: macrolides, ciprofloxacin, rifampin
	Antiviral: acyclovir, ganciclovir
Pancreatitis	NRTI: abacavir, didanosine, lamivudine, stavudine, tenofovir
	PI: lopinavir/ritonavir, ritonavir, saquinavir, tipranavir
	Antibacterial: sulfonamides, ciprofloxacin
	Antiparasitic: pentamadine

NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

Metabolism

Increased energy metabolism of HIV-infected children can contribute to malnutrition by increasing the child's caloric demands to maintain weight and sustain growth. Total daily energy expenditure is the sum of energy needed to maintain a child at rest, the energy needed for activities of daily living, the thermic effect of food, energy needs for growth, and obligatory energy losses. Measurements of resting energy expenditure through indirect calorimetry and total daily energy expenditure through techniques such as doubly-labeled water studies enable investigators to determine metabolic rates of HIV-infected patients.

There are several studies in the pediatric HIV population which delineate resting or total daily energy expenditure, although more studies have been performed in the adult HIV population. The literature in children with HIV infection generally shows no differences in resting energy expenditure (REE)[7,13,14] or total energy expenditure (TEE)[7,15] between children with growth failure and those with normal rates of

growth. However, these studies have been performed in clinically stable children; metabolism in sicker children is likely to be much higher. One study determined whole body protein turnover in children with HIV and found increased protein turnover is associated with low weight and height.[16] Interestingly, Hardin et al.[17] showed the use of a protease inhibitor in the treatment of HIV resulted in decreased protein catabolism and was associated with improvement in lean tissue mass in HIV-infected children tested pre- and post- therapy.

Cytokines

Elevated cytokine expression may contribute to altered metabolic rates and weight regulation abnormalities in HIV and this hypothesis is supported by experimental and animal studies. The cachectin hypothesis was first described by Beutler and Cerami[18] who noticed that patients with chronic infections have significant weight loss that is associated with hypertriglyceridemia and reduced clearance of triglycerides by lipoproteins. They postulated that a decrease in triglyceride clearance could lead to a decrease in fat storage and wasting of lean body mass as a result of the inability to utilize fats as a reserve source for energy. In animal studies, supernatants from activated macrophages induced weight loss when given daily to rodents.[19] This factor in the supernatant was subsequently isolated and named cachetin; later discovered to be the cytokine, TNF. Other cytokines, such as interleukin-1 (IL-1) and the interferons, have similar effects.

Cytokines are known to alter metabolic processes in non-HIV populations. In patients with HIV, cytokines can cause ineffective use of energy substrates. Hellerstein[20] studied hepatic lipogenesis in HIV-infected adult patients and correlated it with peripheral cytokine levels. Both symptomatic HIV-infected patients with normal CD4 counts and HIV-infected patients with weight loss had elevated hepatic lipogenesis, compared with non-infected controls. Hepatic lipogenesis correlated with interferon-α levels in the fasted state in the patients with HIV infection and weight loss. Other cytokines were not correlated with increased hepatic lipogenesis. In addition to increasing the hepatic synthesis of fatty acids, TNF also mobilizes free fatty acids by stimulating peripheral lipolysis. The net result, “futile cycling”, the process by which fatty acids are shuttled from adipose tissue to liver and back to adipose tissue, utilizes energy inefficiently. The process results in increased metabolic rates, with greater caloric needs to maintain nutrition. The net effect of cytokines for patients

infected with HIV is nonproductive use of energy substrates. Approximately 28% of calories are lost if lipogenesis from carbohydrate precedes its oxidation. Roubenoff et al.[21] found in HIV-infected men that loss of lean body mass was driven by catabolic cytokines and not by inadequate dietary intake or hypogonadism. Other investigators have found similar associations, independent of viral load.[22] Limited studies in children showed increased IL-6 activity, as well as low IGF-1 and increased viral load to be associated with growth impairment.[15] The net effect of elevated cytokine levels may contribute to the relative hypermetabolism seen in HIV-infected patients. Since depression of immune function secondary to malnutrition is potentially reversible, nutritional rehabilitation in HIV-infected children may significantly lower serum cytokine levels by positively improving immunologic function, decreasing opportunistic infection and diminishing HIV replication. This, in turn, would decrease cytokine production. With lower TNF and IL-1 production, promotion of HIV replication would be decreased and the systemic effects of these cytokines such as the wasting and malabsorptive symptoms would be reduced.

PSYCHOSOCIAL FACTORS

Psychosocial factors are also important contributors to suboptimal nutrition of HIV-infected children. An unstable home environment and inadequate emotional and social support have been shown to be a factor for growth problems in both HIV-1-infected[23] and non-HIV-infected children by many mechanisms, including growth hormone deficiencies.[24,25] Children with HIV infection are at risk for living with parents who are ill, who have limited access to social services and support, and who may have ongoing problems with drug and substance abuse. Investigators have found maternal crack and cocaine use during pregnancy to be a predictor of growth and nutritional problems for the child.[26,27] This finding is not unique for HIV, as it has been reported in other non-HIV cohorts.[28] Children born to drug-using women are often small, suggesting that drugs have a prenatal effect, but the postnatal home environment is likely to influence growth as well. Current studies have also found that home care providers can both positively or negatively influence functional status of HIV-infected children.[23]

GROWTH AND BODY COMPOSITION OF HIV-INFECTED CHILDREN

Growth

Impaired growth and malnutrition are common among infants and children with HIV infection and are closely associated with morbidity and mortality in this population.[27,29–34] Even in the era of ART, failure to thrive, defined as weight for age z-score ≤ −2.0 S.D. was common in HIV-infected children in the U.S. and was found in 37% of perinatally infected children at one year of age.[26] In a large cohort of almost 18,000 children in 12 ART programs in sub-Saharan Africa, it was observed that although there was a sustained growth response and catch-up growth in children, after three years of ART treatment not all children achieved normal weights and heights.[35] Furthermore, since even with ART impaired growth has been shown to be associated with increased mortality, independent of age or HIV viral load,[36,37] nutritional status and growth assessment remains vital in the management of HIV-infected children.

Weight loss and gastrointestinal symptoms are one of the most common presenting symptoms of HIV disease in developing countries. In Tanzania, 200 children with severe malnutrition and non-malnourished controls who were matched for age, sex and area of residence, were screened for evidence of HIV infection.[38] Twenty-five percent of the malnourished group was HIV-positive compared with 1.5% of the control group. Since these are common observations routine screening for HIV infection in malnourished children is recommended as part of IMCI guidelines in developing nations.

In developing nations, other confounding factors may exist which can explain different outcomes relating to growth. In one study of 822 HIV-infected pregnant women from Tanzania, low birth weight was associated with maternal advanced stage HIV, however malaria, helmintic infections, and intestinal parasites were also strong predictors of low birth weight.[39] Maternal nutritional status of HIV-infected women receiving ART was associated with low birth weight and stunting in their infants.[40] These data demonstrate the importance of maternal health in fetal growth and birth weight. Interventions to improve maternal health include timely initiation of ARVs when CD4 counts drop below 500 or 350; micronutrient supplementation; good nutrition and psychosocial support. However, with the increased use of highly active or combination antiretroviral therapy (HAART) to prevent mother–to-child transmission, new data on the

increased risk of low birth weight and prematurity associated with HAART has created a concern.[41,42]

In recent years, the importance of breastfeeding for promoting growth in HIV-infected infants has become evident. A South African study[43] which examined growth of HIV-infected and uninfected infants according to infant feeding mode showed that in HIV-infected infants especially, breastfeeding was associated with consistently higher weight z scores than was seen in those infants fed formula milk. This was more pronounced in the first four months and particularly in the first six weeks, where the mean difference was 130 g higher for male infants and 110 g higher for the female infants. These data underscore the importance of promoting WHO recommendations for exclusive breastfeeding in the first six months and continued breastfeeding for at least two years in order to ameliorate the growth deficits associated with HIV infection. Furthermore, these data together with data showing that breastfeeding improves health and survival of HIV-infected infants[44–47] encourage the promotion of community-based human breastmilk banks to supply breastmilk for HIV-infected AIDS orphans.

Body Weight and Composition

Accurate assessment of weight, linear growth, and evaluation of body composition are key components in determining nutritional status in all children. Weight loss or a decrease in growth velocity are simple markers used to diagnose the wasting syndrome in children with HIV infection. However, using weight as the only marker of nutritional status can be misleading, since weight can be confounded by symptoms such as vomiting and diarrhea, which affect hydration. In addition, hydration status and edema can influence weight measurements and obscure the true nutritional condition. Mid-upper arm circumference (MUAC) is a useful and simple tool used globally to determine nutritional status in adults and children. When available, a more accurate measure of nutritional status is body-cell-mass, which refers to the nonadipose cellular mass and is equivalent roughly to the intracellular water volume and can be determined using bioelectrical impedance. The usefulness of bioelectrical impedance measurements is however limited, since it is affected by hydration status of the individual.

Anthropometry and body composition studies can provide insight into the potential etiology of a nutritional disorder. The body's first (and normal) response to starvation (inadequate food intake) is the preferential

loss of body fat, which can be reflected in diminished triceps skinfold thickness measurements or other measurements of body fat. When fat stores are depleted, wasting of lean body mass occurs. In contrast, cachexia or wasting refers to the preferential and inappropriate loss of lean body mass over fat mass, with or without concomitant weight loss. Cachexia has been described previously in patients with cancer, but more recently has been found in patients with HIV infection, including children. Cachexia may be mediated by chemical intermediates such as cytokines and is discussed in the section on pathogenesis.

Earlier studies utilizing various methods to assess body composition have been performed in HIV-infected children. Body composition measurements of 89 children born to HIV-infected women, (52 children were HIV infected) found lean body mass measured by arm muscle circumference was significantly less in the HIV-infected group by 2 years of age. There were no differences in fat mass between the two groups of children.[48] In a cross-sectional study of HIV-infected children treated with nucleoside reverse transcriptase inhibitors, Fontana and colleagues compared bioelectrical impedance measurements of fat free mass (FFM) in 86 HIV-infected children (mean age 6.9 years) with 113 healthy controls (mean age 7.7 years).[49] These investigators found that FFM was lower in HIV-infected children compared with controls, however, when FFM was evaluated as a percentage of total body weight, there was no difference between groups. Weight for age and FFM z-scores <−2.0 were associated with increased risk of death (RR 11.4 and 5.1, respectively), with weight for age serving as a stronger prognostic indicator than FFM. Arpadi and colleagues used dual energy x-ray absorptiometry (DXA) and also found reduced FFM but normal fat stores among HIV-infected children compared with uninfected controls, regardless of whether or not growth failure was also present.[50] These findings indicate that poor growth and decreased FFM are considerable problems for children living with HIV infection and that these parameters have a significant deleterious effect on survival. The introduction of HAART has revolutionized the management of HIV infection in children. Much recent attention has focused on the potential impact of HAART on growth and body composition as well as immune function and survival. Early data from Europe showed clearly that HIV-infected infants were born with lower birth weights compared with exposed-uninfected infants and that their weights continued to diverge until they were commenced on HAART whereafter their growth improves.[51–53]

Nachman and colleagues[54] reported that, in addition to a significant

relationship between HIV viral RNA levels and indices of poor height and weight, the introduction of HAART was associated with improved weight gain. Importantly, height growth achieved essentially normal levels after two years of therapy. Peacock-Villada et al. examining outcomes after HAART treatment of children in both developed and developing countries reported that mortality rates were much lower compared with that before HAART in both settings.[55] However the mean weight for age z-score (WAZ) was significantly lower in children in developing vs developed countries (−2.2 vs −0.4, $p < 0.001$); not surprisingly the mortality rate was higher in children from developing countries. In studies conducted in Zambia,[56] Kenya,[57] and Lesotho[58] of HIV-infected children treated with HAART, lower WAZ and weight for height Z-scores (WHZ) were predictors of mortality. Studies in developing countries also show that although treatment with HAART results in improvements in underweight and stunting the values often do not reach normal values and therefore attention needs to be given to other means of improving these parameters.

There is further evidence that abnormalities in growth parameters may be linked to virologic and immune response to ART. Verweel and colleagues found that both weight and height improved after initiation of HAART, but only in a subset of children who demonstrated virologic response defined as 1.5 or greater log reduction in HIV RNA.[59] Although data show convincing evidence that effective viral suppression and immune reconstitution with HAART can substantially ameliorate the growth deficits in HIV-infected children, unanticipated effects of HAART have been identified including metabolic alterations and abnormal patterns of body fat distribution or lipodystrophy. As will be covered in the next section, further longitudinal information is needed to determine the potential long-term benefits of ART and its effects on growth and body composition.

HIV-ASSOCIATED METABOLIC DISTURBANCES AND LIPODYSTROPHY

Shortly after the widespread introduction of highly active ART (HAART), a constellation of metabolic abnormalities and alterations in body fat distribution were recognized among many HIV-infected patients (Table 44-3). The loss of subcutaneous fat as well as increased adiposity of the abdomen and hypertrophy of the dorsocervical fat pad were reminiscent of congenital and acquired forms of lipodystrophy and this term has been

used in the HIV population. There is increasing evidence that ARV medications, in particular some protease inhibitors and nucleoside reverse transcriptase inhibitors, contribute directly to lipodystrophy and other identified metabolic complications.[60,61]

In addition to significant and often disturbing changes in fat distribution, patients may develop hyperlipidemia, insulin resistance and diabetes.[60,62] The long-term effects of insulin resistance, hyperlipidemia and fat redistribution may require many years to be fully realized, but there is growing evidence of increased cardiovascular disease in HIV-infected patients. The Data Collection on Adverse Events of anti-HIV Drugs (D.A.D.) study evaluated 17,852 HIV-infected adults and found that hypertriglyceridemia and total cholesterol increased with exposure to ARV medications. The study also established increased rates of myocardial infarction with increasing years of exposure to ART.[63]

TABLE 44-3 Clinical and Biochemical Abnormalities Associated With HIV and Its Therapy in Children

Clinical Features	Laboratory Features
Increased abdominal (visceral) fat	Dyslipidemia
Increased waist-to-hip ratio (not reliable in growing children)	Increased triglycerides Increased total cholesterol
Hypertrophy of the dorsocervical fat pad ("buffalo hump")	Increased LDL cholesterol
Fat atrophy	Decreased HDL cholesterol
Loss of fat in extremities	Insulin resistance
Loss of fat of buttocks	Normal to increased serum glucose
Loss or thinning of facial fat, prominence of nasolabial fold	Increased insulin Increased C peptide
No change to increased weight	Decreased glucose tolerance
Fatigue and weakness	Elevated lactate levels

Several studies have been conducted to evaluate whether pediatric patients with HIV infection receiving HAART are also experiencing changes in body fat distribution and metabolic abnormalities. For example, Arpadi and colleagues[64] assessed body fat distribution in 28 prepubertal HIV-infected children with DEXA scans and 29% had evidence of lipodystrophy (defined as fat atrophy and trunk fat accumulation). The

presence of lipodystrophy was positively associated with protease inhibitor use (OR 7.0) and stavudine use (OR 9.0) in this population. A multicenter two-year prospective evaluation of 130 HIV-infected children on ART was completed in Paris, France.[65] Nearly one quarter of the participants had evidence of lipodystrophy. Other metabolic disturbances were frequently identified in this cohort including low HDL cholesterol, increased total cholesterol, and triglycerides. Insulin resistance, defined as a fasting insulin > 95% for normoglycemic children matched for pubertal status, doubled in frequency over the two-year study period from 13.2% to 25.6%. Important predictors of hyperinsulinemia and dyslipidemia were development of puberty, exposure to protease inhibitors and pretreatment severity of HIV disease. More research is needed to determine the effects of HAART on fat redistribution and lipids and glucose homeostasis in children, particularly given the potential life-long exposure to HAART, which may be required for HIV viral suppression. In addition to the potential increased risk of diabetes and cardiovascular disease, children may also experience as yet unappreciated abnormalities in pubertal development, bone health, and kidney function in relation to metabolic complications of HIV and its therapy.

MICRONUTRIENTS

Several micronutrients have been linked to immunomodulation, both in vivo and in vitro. For example, deficiencies of pyridoxine, folic acid, vitamin A, vitamin C, and vitamin E result in impaired cell-mediated immunity and reduced antibody responses. Vitamin B6 deficiency results in decreased lymphocyte response to mitogens, yet a moderate increase in β-carotene intake may enhance immune responses. With zinc deficiency, there is lymphoid atrophy and decreased delayed cutaneous hypersensitivity responses. Likewise, zinc deficiency in animals can reduce the number of antibody-forming cells in the spleen and impair natural killer activity. Clinically, wound healing is impaired in zinc deficiency, whereas, excessive zinc can depress neutrophil function and lymphocyte responses. Iron is important for bacterial growth as well as neutrophil and lymphocytes function. Deficiencies of iron may reduce bacterial multiplication, but may also impair lymphocyte proliferation response to mitogens and antigens. In patients with iron deficiency, lymphocyte response to tetanus toxoid and herpes simplex antigen is low. Overall, in animal models, it is clear that selected vitamin and micronutrient deficiencies impact on immune function in many ways. See

Chapters 8, 9, and 10 for full discussions of trace elements, iron, and vitamins.

Because of the close link between immunologic function and micronutrients, it is logical to expect that low micronutrient levels can affect susceptibility to infection. For HIV-infected children, whose immunologic function is already compromised, further alterations of immunologic function, through micronutrient deficiencies or excesses, may synergistically decrease resistance to infections. Available studies of micronutrients and HIV infection, particularly among children, are outlined in the following sections.

General Studies

There is increasing data available on the micronutrient status of children with HIV infection. Eley and colleagues evaluated 60 HIV-infected children in Cape Town, South Africa and, using blood nutrient concentrations, vitamin deficiencies were frequently identified: vitamin A (80%), retinol-binding protein (85%), vitamin B6 (37%), vitamin E (37%), zinc (20%), and copper (25%).[66] Sixty-two percent of children had two or more deficiencies, and deficiencies were more common and more severe in children older than 24 months. Only 5% of patients were found to have low Vitamin B12 levels.

Anemia is prevalent in HIV-infected children and associated with a poor prognosis.[67] Among Indian HIV-infected children aged 2 to 12 years, the prevalence of anemia was 52.5%.[68] Iron deficiency alone was ascribed as the etiology in 38% of the children and inflammation as the etiology in another 38% of children. Compared with nonanemic children, anemic children were more likely to be underweight and stunted. Children who commenced ART had a significant increase in hemoglobin and if iron supplements were received in addition to ART, children experienced an even greater increase in hemoglobin.

In a large cohort of HIV-infected children and adolescents in the United States (n = 264), there were no differences in intake of vitamins A, C, iron, or zinc, compared with uninfected controls (n = 127).[69] Approximately, one-third of the children studied reported use of a daily vitamin/mineral supplement. The investigators noted intake below the estimated average requirement of the dietary reference intakes (DRI) in 40% of children for vitamin E, 19% for vitamin A, and 10% for zinc. However, there were no identified differences in the prevalence of micronutrient inadequacy when evaluated according to HIV status or CD4

T-cell strata. Therefore, there appears to be important regional variation in the prevalence of micronutrient deficiencies in children.

Vitamin A

Vitamin A is arguably one of the most frequently studied vitamins in relationship to immune function and HIV. In adults, Tang and colleagues[70] showed a relationship between total vitamin A intake and progression to AIDS, but the relationship was U-shaped, the lowest and highest quartiles of intake did less well than the two middle quartiles in terms of progression to AIDS. Data available from HIV-infected children in North America,[71] found vitamin A deficiency to be relatively uncommon and vitamin A concentrations did not appear to be related to mortality in this population.

Vitamin A deficiency and supplementation, however, may have a significant role in HIV disease progression in areas of the world where vitamin A deficiency is more prevalent.[72–77] In a trial of vitamin A supplementation in Tanzania, HIV-infected children experienced a 63% reduction in all-cause mortality with vitamin A supplementation compared with placebo.[72] In a longitudinal observational study of 194 HIV-infected children in Uganda, low plasma β-carotene levels, but not vitamin A levels, were predictive of increased mortality. This and other studies, however, show a relationship between low vitamin A levels and poor growth in HIV-infected children.[72,75] For example, in a placebo-controlled trial of vitamin A supplementation in Tanzania, including 50 HIV-infected children, vitamin A–treated children under 18 months of age experienced a 2.8-cm greater height increase compared with placebo.[77] One potential mechanism for this beneficial effect on growth may be improved gut permeability (i.e., reduced permeability with vitamin A), which was shown with perinatal vitamin A supplementation in HIV-infected infants.[73]

B Vitamins and Folate

Baum and colleagues[78] evaluated vitamin B6 status in HIV-infected adults in the United States. In this study, vitamin B6 deficiency was associated with decreased lymphocyte responsiveness to mitogens and suggested as a cofactor in reduced natural killer cell cytotoxicity. However, vitamin B6 was not related to CD4 T-cell number. In a study of 210 ART-naive HIV-infected adults in Uganda, 10% were identified as vitamin B12 deficient, and among those with a CD4 count ≤ 350 cells/μl, suboptimal B12 levels were associated with a higher mean rate of CD4 decline, compared with

those with normal B12 levels.[79] In an HIV outpatient clinic setting in Nigeria, plasma folate levels were significantly lower in HIV-infected compared with uninfected controls, and folate correlated positively with CD4 count and inversely with HIV viral burden.[80] Intestinal absorption of folate and other nutrients may be responsible for abnormal blood levels. Folic acid absorption was studied in 25 HIV-infected patients after an oral folic acid dose, with blood samples taken sequentially over three hours.[81] Absorption of folic acid was significantly impaired in patients, regardless of the stage of the disease. Thus, intestinal absorption of folate and other nutrients may be responsible for abnormal blood levels.

Supplementation with B vitamins, vitamin C, and vitamin E was evaluated in a large clinical trial of pregnant HIV-infected women in Tanzania. In addition to improved birth outcomes (lower risk of both preterm delivery and low birth weight), maternal supplementation was associated with lowered infant morbidity and higher CD4 counts[82] as well as a reduced rate of mortality and AIDS progression in mothers.[83]

Antioxidants

Oxygen-free radicals are generated during normal metabolism, yet their production may increase during infection, malnutrition, stress, or drug therapy. Endogenous antioxidant activity such as catalase production and exogenous antioxidants (e.g., vitamin E and selenium) may be important in HIV. Selenium is a potent antioxidant and is also an important cofactor for immune function in humans. In vivo studies have shown the importance of this element in protecting cells from HIV activation and the effects of TNF, through increasing glutathione peroxidase activity.[84] In one cross-sectional study, HIV-infected children had low glutathione levels which correlated with CD4 cell count.[85] Low plasma selenium levels were associated with increased risk of mortality of children born to HIV-infected mothers in Tanzania,[86] supporting a potential relationship with nutritional antioxidant and immunity.

Trace Metals

Zinc's role in metabolic function has been well studied. It is important in the stabilization and function of metabolic enzymes including those involved in protein synthesis, catabolism, energy metabolism and RNA and DNA synthesis. Regeneration of gut epithelium, stabilization of brush border enzymes and improved immune function are all proposed mechanisms for zinc's beneficial effects in acute diarrhea.[87] A study by

Graham and colleagues showed that serum copper levels were higher and zinc levels lower in HIV-infected adult patients who progressed to AIDS than in seropositive patients who did not progress.[88] Using logistic regression, they found that higher serum copper levels (odds ratio 2.23 [95% CI 1.02, 4.87]) and lower serum zinc levels (odds ratio 0.3 [95% CI 0.14, 0.66]) predicted progression to AIDS independent of baseline CD4 lymphocyte levels, age, and energy adjusted dietary intake of both of these nutrients. In an open treatment study of HIV-infected children with a CD4 count < 500 cells/mm^3, supplemental zinc was administered for one month.[89] Although 69% of the children had low zinc levels at baseline, supplementation did not have an effect on p24 antigen or CD4 count. The prevalence of zinc deficiency among HIV-infected children, which was estimated at 20% in one South African study,[66] combined with the observed reduction in episodes of watery diarrhea in HIV-infected children who received zinc supplementation compared with a placebo,[90] points to a potential benefit for zinc supplementation in children with HIV.

While there is some evidence of benefit of individual micronutrients, there is no conclusive evidence of benefit for routine multiple micronutrient supplementation. For instance, a recent randomized controlled trial of multiple micronutrient supplementation in Ugandan HIV-infected children showed no reduction of diarrheal morbidity associated with supplementation.[91]

Another trial among 2387 HIV-exposed Tanzanian infants (all of whose mothers received micronutrient supplementation during pregnancy and lactation) showed that infant micronutrients did not reduce all causes of mortality such as episodes of diarrhea, but did reduce episodes of fever and vomiting. Among 429 children whose mothers received ART, multivitamin use was associated with a significant reduction in hospitalizations (P = .035), episodes of fever (P = .005), and episodes of fever and cough (P = .019) compared with placebo.[92]

DIAGNOSTIC EVALUATION

Malnutrition and wasting are common in HIV-infected children, and therefore routine nutritional assessment should be performed at regular intervals, particularly under 24 months of age, in every child who is at risk for HIV infection. Careful consideration of the pattern of growth will lead to an investigation of nutritional versus endocrine dysfunction. Subtle changes in growth and altered nutrient intake can be detected. The

nutritional assessment should include measures of weight, height, head circumference, triceps skinfold thickness (to measure fat mass) and MUAC (to assess muscle mass). A detailed dietary history and recall should be ascertained regardless of the child's nutritional condition. Dietary advice or encouragement should be reinforced at each visit. Figure 44-1 outlines a clinical algorithm of diagnosis and management of HIV-infected children with nutritional abnormalities.

If a child shows evidence of malnutrition (Table 44-4), nutrient losses should be evaluated in addition to nutrient intake. Clinical symptoms should be determined with the focus on gastrointestinal problems, such as vomiting, abdominal pain, and diarrhea. A complete physical examination will provide additional important clues. The child should be evaluated for oral thrush, abdominal pain, and gross or occult blood in the stool. Laboratory studies may include a complete blood count, liver function studies, pancreatic enzyme levels, and a complete evaluation for enteric pathogens. When resources are available, studies such as a radiographic upper gastrointestinal contrast series, upper gastrointestinal endoscopy, and an abdominal ultrasound may provide a definitive diagnosis. If clinical symptoms warrant, a gastrointestinal absorption evaluation may be performed; including a lactose hydrogen breath test, d-xylose absorption study, and/or 72-hour fecal fat collection.

Serum micronutrients may be assessed in malnourished or wasted HIV-infected children. Consider measurements of vitamins A, E, and D, especially if there is liver, biliary tract or pancreatic disease. Serum zinc and selenium can also be measured and may be low; if so, they should be replaced to optimize immune function.

It may also be useful, where able, to evaluate a child's energy needs. Although the use of doubly labeled water as a measure of total energy expenditure remains a research test, clinical centers are increasingly able to perform indirect calorimetry as a bedside test of resting energy expenditure in children. In a practical sense, the best estimation of energy needs for an HIV-infected child is the child's response to a diet enriched in calories, with accurate documentation of caloric intake and type of food.

Among HIV-infected children receiving chronic ART, it is also important to monitor for potential changes in body fat distribution and abnormalities in metabolic parameters that have been linked to the use of HAART. For example, skinfold thickness measurements obtained using standardized calipers by trained bionutritionist can be effective in identifying and monitoring peripheral lipoatrophy.[93] This combined with annual anthropometric assessment of waist and hip circumference with

calculation of a waist-to-hip ratio may be very useful in detecting alterations in body fat distribution that develop over time with exposure to HAART. Noninvasive measures of body composition (bioelectrical impedance, air displacement plethysmography) may also be helpful in some settings.

It is currently recommended that HIV-infected adults have fasting serum glucose and lipids checked prior to initiation of ART and then repeated biannually after initiation of therapy as well as following any changes in ART. While there are no HIV-specific recommendations for performing more detailed screening for diabetes, such as on oral glucose tolerance testing, this may be beneficial in cases where there is concern for insulin resistance or documented impaired fasting glucose (fasting glucose > 100 mg/dL).

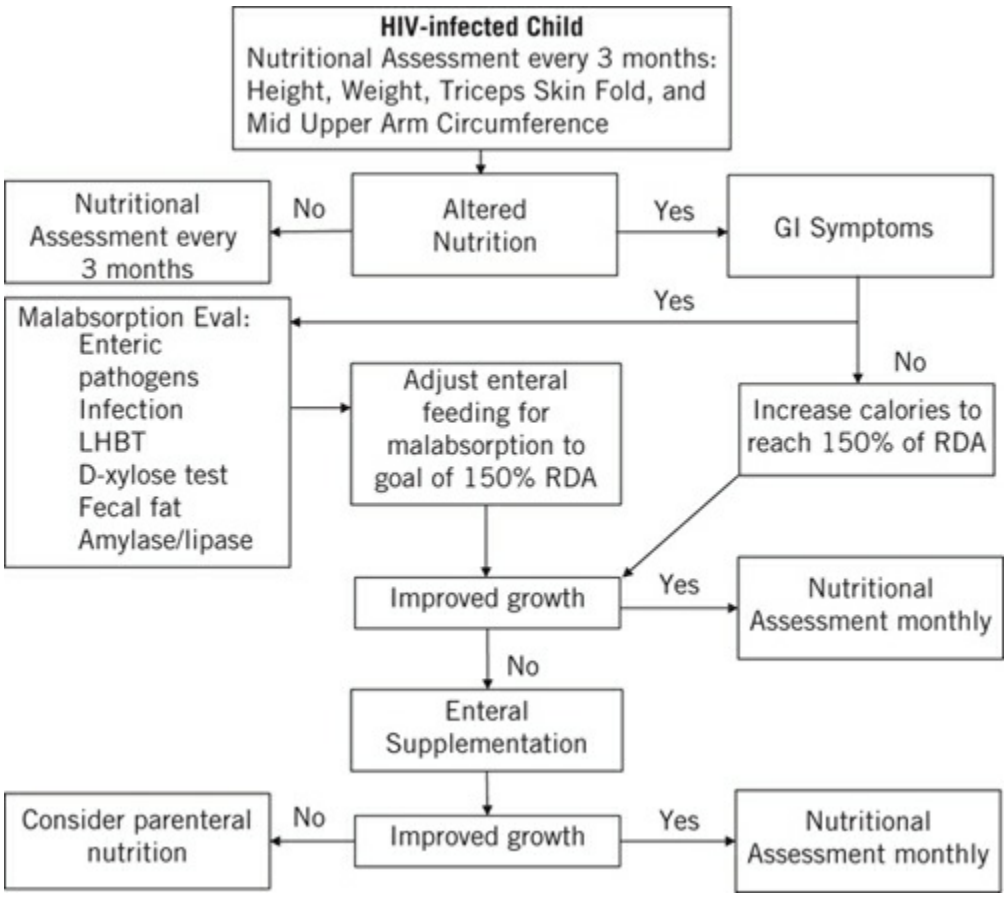

Figure 44-1 Algorithm for monitoring, diagnosing, and treating malnutrition associated with human immunodeficiency (HIV) disease in infants and children. GI, gastrointestinal; LHBT, lactose hydrogen breath test; RDA, recommended dietary allowance.

TABLE 44-4 Clinical Indicators of Malnutrition in HIV-infected Children

Measurements
Weight growth velocity < 5% for more than 2 months
Decrease in 1 major growth percentile for weight
Weight or weight-for-height percent standard < 90%
Weight-for-height < 5th percentile
Loss of > 5% of lean body mass
Serum albumin < 3 g/dL

Nutritional Interventions

Oral Supplementation

Nutritional interventions should be instituted when the child fails to meet growth standards as defined in Table 44-4. In general, a proactive approach to nutritional guidance is preferred when early nutritional interventions are more effective than during the later stages of HIV disease. Nutritional therapies should be instituted in parallel with treatment for other ongoing systemic or gastrointestinal diseases. Oral nutritional therapies, in most patients, should be tried initially. Formula caloric density should be increased by concentration or adding sunflower oil. If the child is eating solids, adding extra fat in the form of butter, margarine, peanut butter, or sunflower oil may be helpful. Since a precise estimation of caloric needs is usually not available, the caloric goal, in general, should be targeted at 50% above the RDA for age and sex for a child with growth failure. Other nutritional requirements are shown in Table 44-5, although these requirements are considered minimal, and more may be required if the child has clinical and biochemical evidence of nutritional deficiencies. Formula composition should be prescribed according to the extent of nutrient malabsorption. If a child has clinical symptoms indicating malabsorption of lactose (e.g., diarrhea, bloating, flatulence), a lactose-free diet is indicated. Caution is advised, however, in prescribing a lactose-free diet if the child has no clinical symptoms of lactose malabsorption, as limiting lactose may also restrict the foods that are the most enjoyable and richest in energy. In addition, an oral lactase supplement may be added in some cases of lactose intolerance. Yogurt and other fermented milks may also be better tolerated as they have less lactose and are also often more culturally acceptable in developing countries. A protein hydrolysate

formula should be considered if the child has evidence of gastrointestinal mucosal dysfunction with malabsorption of fats and proteins.

A wide variety of food supplements have been tested in studies in HIV-infected children and generally those children that receive supplements have shown better weight gain than those receiving standard nutritional support. A study in South Africa showed that protein-supplemented milk formula improved WAZ and HAZ scores in HIV-infected children with prolonged diarrhea.[94] A Zambian study using an amino acid–based elemental diet rather than the standard skim milk/soy diet showed the intervention diet resulted in HIV-infected children having better weight gain.[95] Ready-to-use-therapeutic food (RUTF) was shown to result in more rapid weight gain in Malawian HIV-infected children compared with maize-soy flour.[96] In Tanzanian children, the provision of RUTF for at least four months was associated with a lower incidence of underweight and wasting compared with children who did not receive RUTF.[97] Although RUTF has gained a wide acceptance and is becoming standard of care for HIV-infected children, there is a dearth of clinical trials justifying it's use, and insufficient clinical evidence showing that RUTF is a better option than ready to use supplementary food or fortified blended foods or other options.[98]

TABLE 44-5 Nutritional Requirements for HIV-infected Children

Nutrient	Requirements Per Day*
Total calories	100%–150% RDA for age and sex
Protein	100%–150% RDA for age and sex
Vitamin A	400–1000 µg retinol
Vitamin D	400 IU
Vitamin E	3–10 mg d-alpha tocopherol
Vitamin K	5–80 µg
Vitamin C	30–60 mg
Thiamin	0.3–1.1 mg
Riboflavin	0.4–1.3 mg
Niacin	5–15 mg
Vitamin B6	0.3–1.6 mg
Folate	25–180 µg
Vitamin B12	0.3–2.0 µg

Iron	6–15 mg
Zinc	5–12 mg
Selenium	10–55 µg

* Requirements reflect the clinical nutritional status of the child; more or less may be needed depending on evidence of deficiency. Ranges reflect variations in needs based on age and sex.

For infants and young children in particular, breast milk is considered the best nutrition since it contains factors that protect the infant against pathogens. Breastfeeding also fosters the maternal-infant bond. Unfortunately, women with HIV infection can transmit the virus to their infant through breast milk and therefore breastfeeding in this circumstance is discouraged in countries with low infant mortality rates where other safe feeding options exist. In developing countries where the majority of HIV-infected women live, WHO recommendations[99] encourage women to practice exclusive breastfeeding during the first 6 months of the infant's life and then to introduce complementary foods while continuing breastfeeding for 12 months or longer as indicated. Breastfeeding women should be provided with ARV treatment at least for the duration of the breastfeeding period and their infants should receive daily nevirapine prophylaxis for 6 weeks post-delivery.[100,101]

Enteral Supplementation

If oral interventions fail, because the child cannot consume adequate nutrients to sustain growth, enteral supplementation should be considered. Nasogastric tube feedings should be instituted first, to document the child's ability to gain weight with supplemental enteral feedings. Complications relating to nasogastric tube feedings include sinusitis and the technical inability of the caretaker to administer the feedings or to correctly position the tube. If delivery of feedings through a nasogastric tube improves growth and feeding is required beyond six to eight weeks, then placement of a more permanent device, such as a gastrostomy tube, should be considered. A gastrostomy tube provides easy access to the stomach with less physical and emotional trauma to the child. In addition, studies show that gastrostomy tube placement results in significant improvement in medication compliance and reductions in medication administration time in children with HIV infection.[102,103]

Prior to the widespread use of ART in the United States, a study of 23 HIV-infected children found that weight and WHZ scores increased with gastrostomy-tube feedings.[104] This increase in weight and weight-for-height was coincident with an increase in caloric intake. Additionally,

children who gained weight with gastrostomy-tube feedings were hospitalized less in the six months after gastrostomy-tube placement and had a 2.8-fold reduction in risk of dying. Guarino and colleagues evaluated the effects of enteral (n = 16) and parenteral (n = 46) nutritional therapy for HIV-infected children with malnutrition and evidence of diarrhea or malabsorption.[105] More than 80% of patients receiving enteral therapy gained >5% of their baseline weight, and enteral therapy was associated with significant increases in CD4 cell count. In addition, enteral therapy improved gut absorption with 75% of patients experiencing normalization in the xylose absorption test. Combined, these findings suggest that early nutritional intervention is indicated in children with HIV infection and may improve morbidity and survival.[106]

Parenteral Nutrition

Parenteral nutrition should be reserved for HIV-infected children who continue to lose weight on an aggressive enteral program, who have severe recurrent or chronic pancreatic or biliary tract disease, or have intractable diarrhea with weight loss. The placement of a central venous catheter can provide venous access that is often difficult to obtain in terminal stages. Central venous catheters present an additional risk for sepsis, and studies in adults and children with HIV infection present conflicting results regarding the risk of infection.

Limited data are available on the benefits of parenteral nutrition (PN) in children with HIV infection. In the series reported by Guarino et al., 46 HIV-infected children with malnutrition and malabsorption received a median of 157 days of PN.[105] While CD4 cell count, weight, and xylose absorption all improved significantly in the patients receiving enteral therapy (n = 16), these measures improved on PN, but not significantly. One possible explanation for the difference in findings between PN and enteral nutritional support is that this was an observational study and patients on PN had more advanced disease as indicated by a lower baseline CD4 count (154 cells/mm^3 for enteral patients vs. 55 cells/mm^3 for PN patients). In addition, 58.7% of PN patients vs. 18.8% of enteral patients died during the follow-up period, which may be related to increased risk of infection with central lines and PN, but may also reflect the practice of reserving PN for late and end-stage patients. In resource-poor settings with more advanced HIV disease, the availability of PN is usually limited as well.

Other Nutritional Therapies

Appetite Stimulants

Megestrol acetate, a synthetic orally active progesterone, widely used to treat breast cancer, has shown promising results as an appetite stimulant in adults with HIV infection. The mechanism of weight gain with megestrol acetate is under investigation, but research suggests that it has an effect both on behavior (i.e., food intake) and metabolism, by the induction of lipogenic enzymes and fat synthesis. There are few reports on the use of megestrol acetate in children with HIV infection. Clarick et al. evaluated the effects of megestrol acetate in 19 HIV-infected children for a median of seven months at doses between 4.0 and 8.5 mg/kg/d and found increased WAZ scores with continued therapy, but no improvement in linear growth.[107] The authors also reported that poor weight gain and/or weight loss occurred after megestrol acetate was withdrawn. Adrenal suppression was also noted in 7/10 HIV-infected children treated with megestrol acetate compared with 0/10 HIV-infected children not on megestrol acetate.[108] Therefore, the use of megestrol acetate may be beneficial for weight gain and improved appetite in HIV-infected children, but caution is warranted particularly when discontinuing or withdrawing therapy.

Dronabinol (delta-9-tetrahydrocannabinol) is another appetite stimulant that has been used in adult HIV-infected patients. It was approved for use in the United States in 1986 for treatment of chemotherapy-induced nausea and vomiting, although it was found to stimulate appetite as well. A randomized, placebo- controlled study of dronabinol was performed on 139 HIV patients. Appetite stimulation, measured by visual analog scale, was maintained or increased in patients receiving dronabinol.[109] After at least 2 months of treatment with dronabinol, 38% of patients gained greater than or equal to 2 kg of weight. Altered mental status was the primary adverse effect for this medication. Currently, there are no dosing recommendations for children.

Numerous other therapies have been employed to initiate weight gain in patients with HIV infection. These include essential fatty acid supplementation (n-3 fatty acids), specific vitamin and antioxidant replacements, pancreatic enzymes, testosterone replacement, and cytokine inhibitors such as pentoxifylline and thalidomide. Additionally, studies are underway evaluating the effects of exercise and aerobic training in patients with HIV infection. Unfortunately, there are no therapies discovered to date that universally prevent or reverse nutritional derangements in HIV-

infected patients. However, the improved nutritional status observed with the use of ART supports the importance of suppression of viral replication and avoidance of opportunistic infections in the maintenance of nutritional health.

There are several ancillary interventions, which should be considered to support nutritional interventions, some of these are listed below:

1. Management of Diarrhea:
   Since diarrhea (especially in children under 2 years of age) is integrally associated with malnutrition, it is important to have adequate diarrheal management programs. Starting with preventative strategies, there should be promotion of improved sanitation and hygiene practices including the use of clean water, handwashing, and use of latrines. Since vitamin A supplementation has been shown to reduce the morbidity associated with diarrheal disease,[110] it is important that HIV-infected children receive periodic supplementation to prevent diarrheal disease and to lessen its severity. WHO recommendations suggest that children should be supplemented with vitamin A twice a year (100,000 IU for infants aged 6–12 months and 200,000 IU for children aged 1–5 years).[111] Furthermore, adherence to Integrated Management of Childhood Illness (IMCI) guidelines with prompt treatment of diarrhea will have an important effect on preserving the nutritional status of the child. WHO recommendations for treatment include low osmolarity oral rehydration fluids and oral zinc supplementation for 10 to 14 days (10 mg/d for infants <6 months and 20 mg/d for those ≥6 months. Children with persistent diarrhea should receive daily multiple micronutrients for 14 days.
2. Deworming of young children in areas where worm infestations are common:
   Since worm infestations often results in poor appetite, and anemia, six monthly deworming is recommended using oral Albendazole (single dose of 400 mg).
3. Improved care and stimulation of children:
   Improved care with appropriate stimulation of children including physical activity and play can help develop and maintain adequate muscle development. This, in turn, improves their sense of well-being, which impacts positively on their appetite and growth.

4. Following nutritional food guidelines:
   Most countries have adapted WHO recommendations and developed locally appropriate guidelines. The WHO has encouraged an integrated approach to the nutritional care of HIV-infected children and have developed guidelines[112] to assist countries to implement such integrated programs, as well as a guide for local adaption of these guidelines at country level in order to reflect local dietary practices.

CONCLUSION

Great strides have been made over the past two decades regarding the detection, prevention, and virologic treatment of HIV in childhood, with the basic understanding of the interaction between nutritional status and HIV becoming better understood. The cause of nutritional problems in patients with HIV infection is complex and likely multifactorial. It is clear, however, that malnutrition of HIV-infected children is among the most serious, chronic, and difficult to treat problems confronting clinicians caring for HIV-infected children, especially in developing countries. Clinicians should be aware of nutritional problems, and close surveillance of nutrition should be conducted on all children who are at risk for HIV infection. Early, aggressive nutritional interventions are indicated in cases of malnutrition. As a treatment strategy, improving nutritional status of HIV-infected children may improve clinical outcome.

While the incidence of malnutrition in developed countries has decreased with HAART therapy, other metabolic problems can arise. The long-term risks of HAART on HIV-infected children are unknown. Close surveillance for the emergence of insulin resistance, dyslipidemias, and premature cardiovascular disease will be important as children with perinatally acquired HIV age into adulthood. Further investigations on the short- and long-term nutritional and metabolic effects of HAART therapy are still underway. Investigators should continue to study the effects of optimal nutrition, lipid management, and healthy life style changes for HIV-infected children.

Obesity in Developing Economies

45

Sumathi Swaminathan, PhD and Anura Kurpad, MD, PhD, FAMS

Now, populations in developing countries appear to be paradoxically at risk of high rates of obesity. One tends to associate developing countries with poverty, and the occurrence of overweight or obesity in these countries appears counter-intuitive. The picture of underweight children needs to be replaced with a picture in which poor countries have both underweight and overweight children. This is the so-called "dual burden of disease" in developing countries, since first, poverty is still difficult to eradicate, and second, economic development is never uniform and usually distorted, such that the benefits of economic growth are enjoyed by only a section of the population, with the attendant appearance of obesity.

Although childhood overweight and obesity rates are increasing at an alarming rate globally with an estimated 43 million, or approximately 7% of children affected under the age of 5 years,[1] the situation is perhaps worse in developing countries or economies with about 35 million children affected.[2] A large part of the world's population lives in developing countries that comprise a large part of Asia (except Japan), Africa, Central and South America. Childhood obesity is alarming in developing countries, since apart from developing risk factors for noncommunicable or chronic disease (NCD) or exhibiting frank signs of NCD such as diabetes or cardiovascular disease earlier in life, the likelihood of childhood overweight and obesity tracking into adulthood, concomitant with an increase in NCD, is a matter of great concern. In addition to the burden of disease, the economic burden of treatment is high as it is usually lifelong, and more often than not, met from personal finances in

developing economies.

The recent increase of childhood overweight and obesity in developing economies has largely been attributed to their economic and nutrition transition, and particularly with increasing urbanization, albeit at different rates in different countries. Therefore, changes in lifestyle and dietary habits, with an increase in food consumption and shifts in consumption patterns, particularly of calorie-dense foods, as well as inactivity, are largely implicated as drivers for this increase.[3,4]

TRENDS IN THE PREVALENCE OF CHILDHOOD OVERWEIGHT AND OBESITY

The prevalence of childhood overweight is highest in developed countries, with prevalences as high as 15% as measured in 2011. However, developing economies also show a trend of increasing overweight and obesity rates, as for example in Africa, where rates have increased from 4% in 1990, to 7% in 2011. Although Asia has a lower prevalence rate of 5%, in absolute numbers, about 17 million Asian children under 5 years of age are affected, versus about 12 million in Africa.[1] The worldwide trend of overweight and obesity in pre-school children suggests that the prevalence is expected to reach 9.1%, that is, approximately 60 million children in 2020.[5] Table 45-1 indicates secular trends of overweight in children below 5 years of age with prevalence estimates based on the WHO Child Growth Standards[6] median of weight-for-height above 2 standard deviations (SD). The dataset included 639 nationally representative surveys from 142 countries/territories conducted from 1985 to 2011.

On the basis of the World Bank's income classification of July 2012 (low income, middle income, upper middle income and high income, based on the gross national income), the rate of increase in overweight and obesity in children below 5 years of age from 1990, for low income and high income countries are similar, although at different levels (Figure 45-1A and B). Prevalence estimates among low-income countries are reaching the level of lower middle-income countries, but in absolute numbers, there is a threefold increase in obesity and overweight in low-income countries.[1]

Between the ages of 5 and 19 years, a global prevalence of about 10% has been reported with prevalences over 15% reported in Brazil, India, and Mexico (7). In Brazil, between 1974–1975 and 1996–1997, overweight and obesity in 6- to 18-year-old children increased more than threefold,

from 4.1% to 13.9%, in China from 0.93% to 14.9% in boys and from 1.6% to 8.9% in girls between 1985 and 2000 and in 14- to 17-year-old children in India from 9.8% to 11.7% between 2006 and 2009 (7). Although in developed economies, child overweight and obesity have increased particularly in lower income households and in ethnic minority groups; in contrast, in developing economies as in India and China, the rates have risen rapidly in the urban areas and in high-income households.[7,8]

The problem with childhood obesity is that it is likely to track into adulthood, and with the development of risk factors early in life leading to adverse consequences later, these trends are alarming. Understanding biological factors associated with obesity, as well as societal drivers are important.

EARLY LIFE CYCLE FACTORS

Birth Weight and Breastfeeding

Of 18 million infants born of low birth weight (<2500 g) worldwide, 9.3 million are born in South Asia and 3.1 million in sub-Saharan Africa.[9] Both low birth weight, which reflects the pattern of intrauterine growth, and subsequent rapid catch-up growth during infancy, are associated with obesity, metabolic syndrome, dyslipidemia, hypertension, and insulin resistance later in life. The developmental origins of health and disease hypothesis propose that the early fetal environment programs metabolism of the individual, organ growth and functional development, thus affecting physiological functions at various stages of the life cycle.[10,11] This could explain why populations in developing countries like India and China, which are undergoing rapid nutrition transition, are also showing an increased prevalence of NCD including cardiovascular disease and diabetes.[10]

Infants born with intrauterine growth retardation (IUGR) are characterized by fetal hypoglycemia, possibly to maintain the maternal/fetal glucose concentration gradient and transport of glucose across the placenta to the fetus. In turn, this hypoglycemia limits insulin secretion, initiating fetal glucose production, but subsequently results in increased protein breakdown and decreased protein accretion, limiting the growth of lean body mass.[12] There is some evidence that Indian infants are born of low weight and low ponderal index but are of higher adiposity compared to Caucasian babies, the so-called “thin-fat” Indian infant, and that this continues further even later in life.[13] This phenomenon has not been shown consistently in other developing countries,[14] but if it is so, it indicates that the propensity to accrete fat and become overweight is high in such babies.

Although the early programming of metabolism and the propensity for weight gain are relevant to gaining excess weight gain after birth, it will also certainly depend on a number of factors that operate after birth. Immediately after birth, breastfeeding may protect a child from later weight gain and obesity, since it is possible that self-regulation of milk intake may be better in breast-fed than in bottle-fed infants. As much as this may seem intuitive, however, along with reports that exclusive breastfeeding causes a 20% reduction in obesity compared to exclusive formula feeding,[15] this effect has not been confirmed in randomized, controlled trials.[16]

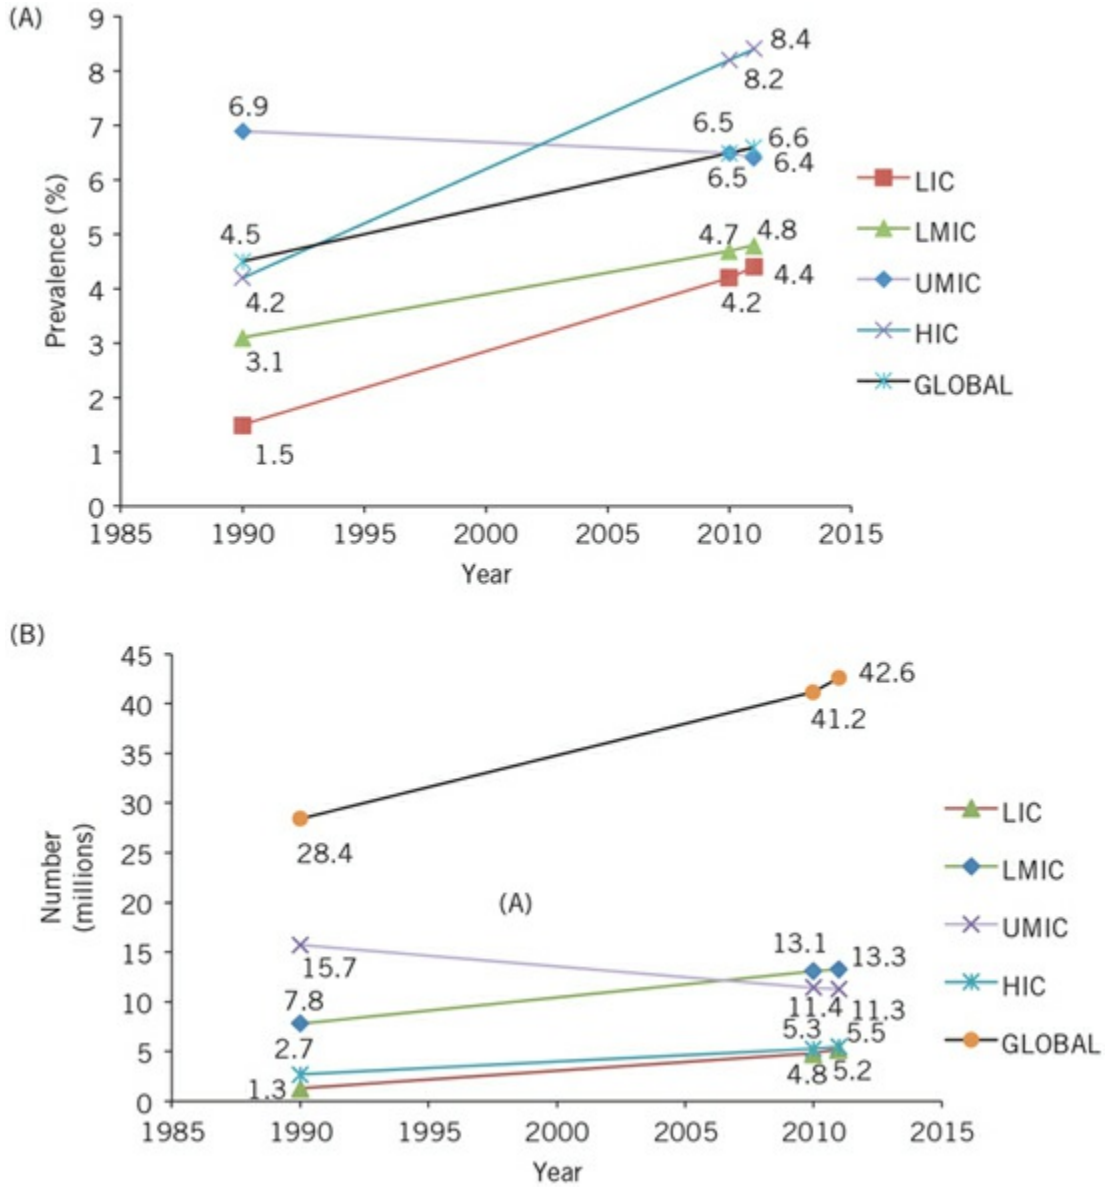

Figure 45-1 (A) Prevalence estimates of overweight and obesity in children below 5 years of age by countries classified based on world bank income group (years 1990, 2010, 2011) (B) Absolute numbers of children below 5 years of age with overweight and obesity by countries classified based on world bank income group (years 1990, 2010, 2011) LIC, Low-income countries; LMIC, Low middle-income countries; UMIC, Upper middle-income countries; HIC, High-income countries. (Data from UNICEF-WHO-The World Bank, 2012.[1])

Markets are also relevant, since mothers who want the best for their baby will be influenced by their peers, and may even get their education about a child's needs from the labels on complementary food packaging. The latest and more accurate Food and Agricultural Organization/World Health Organization/United Nations University consultation[17] on energy requirements has reduced the energy requirements of infants from 104 to 80 kcal/kg/d. On the basis of this definition, an analysis of the amount of complementary feed required (in commercial forms) would literally mean about one less feed if the new norm were followed. However, a recent study in India found that complementary feed packs were still being labeled to meet the older and higher energy requirements.[18] This problem would be trivial if women did not pass on feeding information from labels in their own peer networks, or if health education efforts were up to date and effective, or if women fed their children with foods prepared at home. Social conditions in the current world are such that that middle-class working women in developing countries look toward convenience and time-saving, and as a result, commercial complementary feeds are used more often than not in middle-class households, where the problem of childhood obesity is at its most relevant.

Rapid Catch-Up Growth and Adiposity Rebound

Growth in infancy up to 1 year and during childhood above 2 years of age have been found to be critical periods related to adult body composition, where rapid weight gain in infancy has been associated with higher lean mass in adulthood, while rapid weight gain above 2 years of age with higher fat mass.[11] A study of 1400 adults in New Delhi, India,[19] indicated that children with early adiposity rebound of 5 years or younger had the highest body mass index (BMI) in later childhood and this persisted into adulthood. Aggressive nutrition interventions, which are operational in many developing countries, that target undernourished children in early

infancy to ensure rapid catch up growth, could lead to adiposity and consequently to metabolic syndrome and other chronic diseases both in childhood and adulthood.[20] Relevant here are cultural norms and health education, given the concern of anxious mothers that their child's weight is an index of their health, and that the more their baby weighs, the healthier they are.

Stunting

In general, obesity is related to prosperity, but the relationship between stunting and obesity may be particularly operative in the context of developing economies, where children who were stunted during their earlier life are exposed to energy-dense foods and lower activity levels later on. An analysis of national surveys of Russia, Brazil, South Africa, and China showed that stunting was associated with being overweight among children[21]; similar findings were observed in young Mexican children.[22] However, this association is not uniform, for example, in Indonesia, stunting and lower socioeconomic status were more related to being underweight rather than overweight,[23] whereas in Guatemala, long-term improvements in height were not associated with equivalent increases in BMI.[24] In a Brazilian cohort of boys, stunting at 2 and 4 years of age was not associated with lean mass, or the ratio of fat to lean mass, during adolescence,[25] contrary to what has been reported in cross-sectional studies. Differences in economic development and access to energy-dense foods will confound the relation between stunting and overweight. In addition, it is important that this relationship is examined in longitudinal cohorts rather than a series of cross-sectional studies, as are available in many countries. Small errors in the measurement of height can also confound these analyses.[26] One potential mechanism that has been proposed for this putative relationship is that childhood nutritional stunting is associated with impaired fat oxidation, resulting in increased body fat in such children, and which is a factor that predicted obesity in other at-risk populations.[27,28] This phenomenon is still worth considering as economies develop, when the promotion of optimal growth of children is as important as preventing obesity.

DRIVERS OF CHILDHOOD OVERWEIGHT AND OBESITY

With rapid increases in the prevalence of overweight and obesity over the

past two to three decades, it is obvious that apart from genetics, the environment in which an individual lives must be contributing significantly to this rise, largely due to an imbalance between energy intake and expenditure. To maintain weight, a balance between energy intake and energy expenditure is necessary; a positive energy balance promotes weight gain. Energy intake and expenditure are very variable on a day to day basis. Although energy intake could vary in any of the proximal constituents of the diet, the most variable part of energy expenditure is physical activity. As a result, body fat and muscle mass are the two changeable or plastic elements of the body composition that are affected: excess energy is stored by the expansion of body fat, while muscle mass may be lost as physical activity is reduced.

An increase in energy intake and reduction in physical activity presumably increases overweight and obesity in children, although energy balance is determined by complex biological, behavioral, cultural, social, and environmental factors.[8] The problem is that measuring energy intake or expenditure with any degree of accuracy is difficult. This becomes relevant when one considers that weight gain is not acute, but occurs over a long period of time, in which a positive energy balance as small as 50–100 kcal/d may lead to significant gains in weight. Measuring energy intake or expenditure with our current tools to detect such a small imbalance is virtually impossible in the free world. Further, physiological adaptations in energy expenditure occur when energy intake is different from the actual required energy expenditure. For example, if energy balance is positive, energy expenditure may also rise over time through increments in muscle mass, with a new energy equilibrium achieved. Similarly, when energy balance is negative, adaptations to decrease energy expenditure are activated (e.g., a lowered basal metabolic rate), such that the energy balance is once again achieved.

Dietary Intake

At the individual level, overweight/obesity is due to a positive energy balance, with more calories consumed than what are expended daily. This is influenced by personal choices in everyday life, such as dietary habits and physical activity, and in turn, societal drivers such as urbanization, industrialization, and affluence shape these individual choices. For example, decreased occupational and environmental physical activity requirements have presumably led to a fall in daily energy expenditures. At the same time, more food is being produced than ever, and is available for human consumption.

With the growth of the food-processing industry, this abundance has translated into increased availability and access to energy-dense foods, even in developing nations. Rapid globalization has resulted in changes in patterns of food intake with the availability of refined, high-fat (particularly saturated fats) and high-sugar content foods being more easily available in most of the developing countries of the world.[4] In a study among 6- to 16-year-old children in India, a higher frequency of intake of fried foods was associated with a threefold greater risk of being overweight.[29] In urban India, and this is reflective of developing countries in general, the frequency of fast food, snacks, and bakery food consumption is rapidly increasing due to the attractiveness of fast food, large portion sizes, and easy access. Behaviors at home are also important, because negative behaviors such as eating while watching TV, snacking between meals, and regular dining out are related to overweight,[29] while some studies have shown a protective effect when family meals are eaten without simultaneously watching TV.[30] TV viewing is both a sedentary behavior and a source of exposure to food advertising for children.[31] Detailed data on diets of children in developing economies have not been reported yet. In general, however, the consumption of milk and meat products in the developing world has escalated.[3] This benefits infants and children in the first few years of life as the quality and quantity of protein as well as mineral and vitamin intakes improve, but higher intakes could lead to increase in saturated fatty acid and cholesterol intakes. This trend is now visible in developing countries.[3]

The problem with measuring food intake across populations is that surveys at scale are by necessity fairly broad and simple and are usually based on reported quantities of use and expenditure at the household level, which will not reflect actual consumption, but also will make it impossible to estimate intakes for different age groups in a population. Further, there is poor characterization of processed foods and food consumed outside the home. Even so, at least in India where obesity rates in children are showing an increase, surveys of food intake have actually documented relatively little change in the daily energy intake, but also a gradual decrease in the daily consumption of cereals and pulses, indicating substitution with other sources of energy such as fats.[32] With economic progress, such changes in dietary patterns have only been accentuated. The point is that energy intakes do not seem to mirror the gradual progression in overweight rates; while this may reflect the inability of surveys to accurately account for the increasing contribution of processed foods and

food consumed outside the home toward the daily energy intake, the problem may be due to positive energy balances emerging from falling energy requirements in an increasingly sedentary lifestyle.

Other important drivers are economics and agricultural policy. A balanced diet includes healthy proportions of fruits and vegetables, as well as low amounts of dietary fat. When one considers the intake of fruits and vegetables, however, available figures may be misleading. In India, for example, surveys indicate that dietary vegetable intake has increased by about 50% over the last two decades,[33] but in reality, this increase is mainly in the intake of potatoes and onions, whose nutritive value is relatively poor, especially with regard to micronutrients. In addition, vegetables and fruits are not stored effectively in developing economies, and therefore their prices are subject to large fluctuations depending on production and demand. As a consequence, the food consumption patterns of many poor homes are monotonous because they are simply reflective of these fluctuations, which limit the ability to have a varied dietary intake. On the other hand, there has been a sharp contrast in the pattern of intake of oils and fats: again, giving India as an example, there has been a 25% and 67% increase in consumption of oils and fats in rural and urban areas, respectively.[33] Other obesogenic trends include an increasing consumption of processed foods, snacks, fast food, and sweetened beverages, and a decrease in the number of meals eaten at home.[29]

What could be driving these dietary consumption patterns? Some factors can be deduced from agricultural policy: cash crops account for the greatest increases in area under cultivation. The production and yield among all food groups over the past 50 years in India has been for sugarcane and oil seeds.[34] Another important macroeconomic influence on consumption patterns is food price stability; this is variable across countries and depends on seasonal patterns, successful agriculture initiatives, and other factors.

Physical Activity

Regular physical activity is a metabolic need and influences the growth and development of children and adolescents. Over the past three decades, the use of technology in the activities of daily life has increased and consequently daily activity levels of children have also decreased. Spontaneous physical activity and the use of active transportation have declined with increased urbanization. Built environments in cities do not promote active living. With many parts of the developing world

undergoing rapid urbanization where over half of the world's urban population lives in Asia,[35] it is evident that the physical activity of children is affected.

The global school-based health survey (GSHS) conducted across 55 countries in the world indicates that in most of the developing countries approximately 20% of children 13–15 years of age are active while 30%–40% of children are inactive (that is, spending more than 3 h/d sitting, watching television, playing computer games, or doing other sitting activities).[36] Globally, about 80% of 13- to 15-year olds do not engage in the recommended level of ≥60 minutes of moderate to vigorous physical activity per day. This proportion was seen in over 56 of 105 countries in boys and 100 out of 105 countries for girls.[37]

Increased sedentary activity and increased sleep duration (within limits) have opposite effects on childhood weight status. The effect of sleep debt may probably operate through both direct metabolic effects and indirect pathways by disrupting hormone signaling pathways notably the activation of growth hormone-releasing hormone and inhibition of corticotrophin-releasing hormone which in turn mediates the release of pituitary-derived and dependent hormones such as human growth hormone and cortisol.[38] Short sleep duration is also thought to act through the modulation of leptin and ghrelin.[39] The passive viewing of screens, whether television or computer, can also have strong effects on the risk for overweight and obesity. In a study on urban and semi-urban children in India, increased television viewing of greater than or equal to 1.5 h/d was significantly associated with a risk for overweight compared to children viewing for ≤45 min/d.[40] This increased risk of obesity with a doubling of viewing time in effect means that something more than simply sitting in front of a screen is operational; in this context, behaviors such as eating and watching the screen at the same time can lead to passive overconsumption of energy. In addition to these behaviors, parental BMI, especially maternal BMI, is a known risk factor for childhood obesity,[41] and is likely to reflect the clustering of risk behaviors in families and genetic factors that affect obesity.

School-age children with a marginal to poor nutritional status have a lower total daily energy expenditure and lower energy expended through physical activity. This leads to poor physical performance mainly due to the small body size and lower muscle mass.[36] The lower daily physical activity is likely to happen in school as well as out of school. A recent longitudinal study among adolescent urban school children in India noted a

significant decline in moderate to vigorous physical activity within the course of a single year.[42] This may be because schools simply do not put much emphasis on physical activity and fitness, or do not have the means to do so in poor countries. Equally, there is also the need for excellence in academically competitive environments; this leads to children being made to choose extracurricular academic programs rather than sport in their extracurricular time.

Physical and social features of the urban environment are also known to influence physical activity levels. Actual access to open spaces or parks for leisure-time physical activity is poor in most developing countries, leading to poor walkability. Unplanned urban development, daily access to workplaces, schools and recreational facilities have become increasingly time consuming and dependent on motorized transport. As a case study, in India, while the population of six major metropolitan cities increased 1.9 times between 1981 and 2001, the number of vehicles increased by 7.8 times.[43]

Urbanization and Migration

In developing economies, the urban–rural divide in terms of overweight prevalence is often striking. Urbanization is associated with changes in dietary intake and energy expenditure patterns due to factors that have been explained above. However, increasing childhood obesity is also related to the relocation of populations for more prosperous livelihoods and the drivers of such migration. When there are no serious attempts by governments to increase agriculture and rural economies, concurrent with a push for urbanization, it is obvious that people will migrate from villages in search of better livelihoods offered by the services and industry sectors, which are concentrated in towns and cities. In many countries, this has led to a growing prosperity, and emergence of more middle- and high-income households, and an analysis of survey data in India[44] has shown how the BMI distribution of rural–urban migrants can shift toward the right as their duration of urban living increases (Figure 45-2). Migration is therefore a significant trend of population shift, but without planning, can lead to serious urban poverty as well.

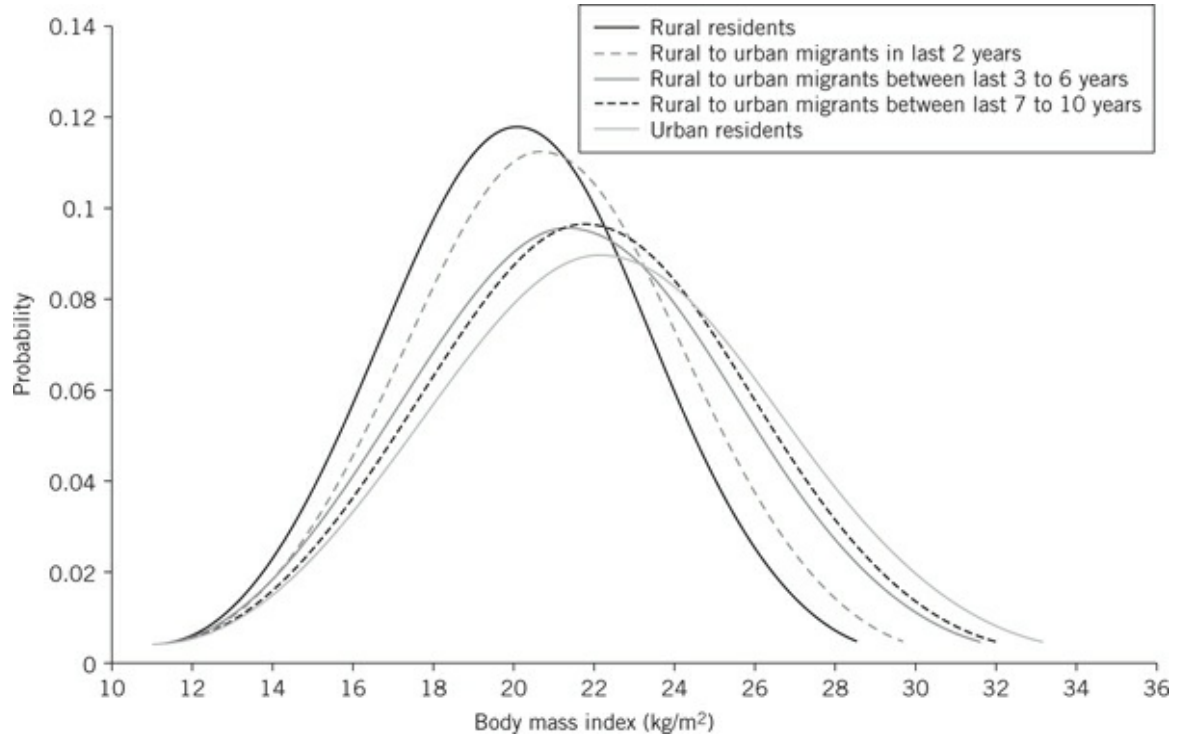

Figure 45-2 Probability distribution of BMI in rural–urban migrant and nonmigrant Indians. (From Kurpad Av, Varadharajan KS, Aeberli I.[45]) Distribution of BMI in populations migrating from rural to urban areas, stratified based on the number of years since migration. There is a continuous right-shift over time, with the BMI of migrants approaching the urban resident (nonmigrant) BMI.

Overweight/obesity rates are higher among those belonging to these higher socioeconomic groups. A recent analysis of nationally representative data from 38 low- and middle-income countries has indicated that higher risk of obesity in urban areas is driven by higher individual- and community level socioeconomic status in urban areas rather than urban living alone.[45] Even so, it is important to point out that these risk patterns are in concurrence with the trends that were observed in developed economies just two decades earlier. In this scenario, risks in the developed nations are believed to have reversed, with the greatest burden among rural residents and disadvantaged groups[46–49] and this shift is estimated to occur in developing countries when the per capita gross national income exceeds US$ 2500.[50] Brazil, an emerging economy, where obesity has spread rapidly among lower economic groups along with economic progress in the last decade, presents a case in point.[51]

POSSIBLE SOLUTIONS AND INTERVENTIONS

Earlier Country Experiences

Many countries have put public health interventions in place to address overweight and obesity; experiences from Chile and Singapore can yield lessons for developing economies. Chile is an example of a country with high levels of child undernutrition in the 1960s, which attempted to eradicate hunger but, inadvertently caused a rise in overweight/obesity. Singapore is an example of a prosperous country, which put in place strategies to combat overweight/obesity.

Chile underwent rapid modernization and economic growth in the early 1990s. Although great progress was made in public health and the prevalence of undernutrition, there was a negative impact with sedentary lifestyles and changes in dietary patterns. Growing incomes in the lower income groups were associated with corresponding increases in purchase of high-fat/high-carbohydrate, energy-dense foods.[52] Undernutrition among children below 6 years in Chile fell from 37% in 1960 to 2.9% in 2000, owing chiefly to the National Complementary feeding programme (PNAC), which focused on poor urban[53] (see Chapter 15 for details). This program delivered basic food supplements and rice to benefit all family members, to prevent redirection of food meant for infants. High coverage and well-established monitoring systems ensured that undernutrition was brought down to negligible levels by 1990, but distribution of food supplements to beneficiary households continued.[53,54] A small but nonsignificant gain in length for age of children was noted in a program evaluation in 1990, but weight for age and weight for length had increased significantly.[53] Studies based on accurate estimations of energy expenditure concluded that an excess of 200 kcal/d of energy was being supplied per child.[55] This could explain the twofold increase in overweight and obesity among children entering school between 1987 and 2000 (Figure 45-3).[55] Feeding mildly stunted children is thought to have contributed to overweight and obesity; however, the target-weight gain criterion, while being sensitive enough, was not specific for determining the need for food supplementation. The lesson to be learnt is that providing additional energy to all, through universal feeding programs, may promote obesity. Therefore, targeted approaches, though not easy, may be more important if obesity is to be prevented.

Singapore launched its National Healthy Lifestyle Program in 1992 to spearhead national strategies based on public education campaigns that focused on physical activity and healthy eating.[56] Official dietary and

physical activity guidelines were formulated, and health promotion grants and awards were instituted to sustain efforts in schools and workplaces. Media campaigns and events were used to raise awareness in the general public.[57,58] Programs also encouraged physical activity in all students, and targeted weight loss in overweight children through mandatory participation in intense exercises and food ration coupons that limited calories consumed during recess breaks. The consequent drop in the prevalence of overweight from 11.7% to 9.5% between 1993 and 2006 was partly attributed to this,[59] However, following reports of stigmatization, bullying and increase in eating disorders attributed to this program, the Holistic Health Framework focusing on general well-being of students was adopted in 2007. The Model School Tuck-shop Program in 2003 provided schools with healthier food service guidelines and placed restrictions on access to energy-dense foods, while similar initiatives were introduced at workplaces and for the general population.[57] The impact of such strategies is hard to ascertain, however, overweight/obesity rates seem to have stabilized or are falling in children and youth.[57,58]

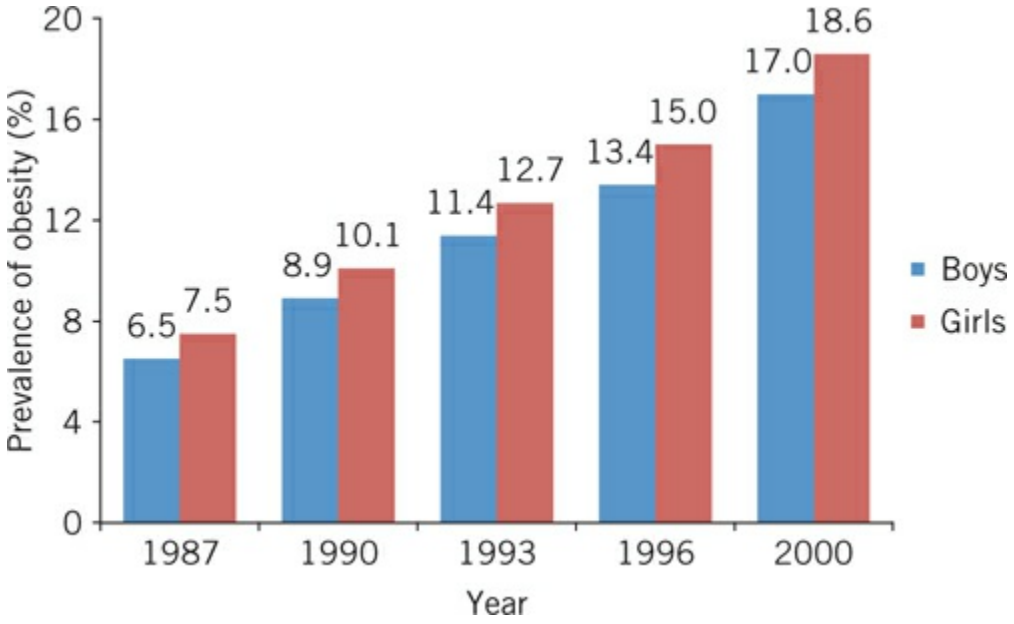

Figure 45-3 Prevalence of obesity in first-grade school children in Chile 1987–2000. (Adapted from O'Leary.[53])

Other countries intervening in the obesity epidemic also initially prioritized school-based strategies. Some of these strategies and their

limitations are outlined in Table 45-2. Coordinated national programs, such as “Agita São Paulo” in Brazil, “Vuka” in South Africa and “Let’s Move” in the United States, using a mix of strategies, are examples. Partnerships with the food and beverage industry are growing, in such areas as product reformulation (low salt, low saturated fats), portion size reduction, healthier menu alternatives, limiting targeted advertising, and nutritional labeling, along with initiatives in urban design and transport planning. Different countries may need different solutions; for adults, a modeling study in 2010 focused on interventions to promote healthy diets and physical activity in the BRIC nations found that the most cost-effective strategy in chronic diseases control was education and counseling by health workers.[59] Interventions targeting children were shown become cost-effective only in the long run as would mass-media campaigns. In the absence of locally relevant evidence, a broad-based strategy aimed at chronic diseases control, focusing on lifestyle changes should be the most sensible option.

In conclusion, with developing economies undergoing rapid increases in urbanization and changes in lifestyle, there is an increase in the prevalence of childhood overweight and obesity. This could track into adulthood and escalate the existing high rate of noncommunicable diseases even further in such populations. In turn, this would exert more strain on their economies, particularly because most of these countries already struggle with a high burden of undernutrition through the life cycle. Within countries, increasing weight is socially and culturally linked to prosperity, because the prevalence of overweight and obesity is higher among the higher socioeconomic groups rather than the lower socioeconomic groups, unlike in developed countries. Obesity prevention programs therefore need to be nuanced, based on socially and culturally accepted models of creating awareness, and targeted at educating individuals, communities, and populations.

TABLE 45-2 School-Based Strategies for Addressing Overweight and Obesity

	Strategy	Components of Strategy	Efficacy and Impact on Obesity/Overweight	Hindering Factors
1	Health education	Dietary and physical activity education	i. Consistent, but small positive effects on behavior	i. Lack of trained personnel in schools

			ii.	Evidence on change in BMI is limited, inconsistent	ii. Already crowded academic environment
2	Regulation of food environment in schools	i. Setting nutrition guidelines ii. Pricing strategies iii. Regulation of food and drink availability	i.	Consistent decreases in availability and consumption of high sugar/fat food in schools	i. Lunch meal scheme function poorly
			ii.	Increased availability of fruits	ii. Regulation of sale around schools will be difficult as trade is unorganized
			iii.	Evidence on change in BMI limited	
3	Regulation of physical activity environment in schools	i. Increase in frequency and duration of physical education classes ii. Development of physical activity infrastructure iii. Footpaths and bicycle ways in school vicinity	i.	Significant increases in time and intensity of physical activity, energy expenditure and aerobic capacity	i. Many schools lack playgrounds ii. Many urban schools exist in crowded environments and development of play grounds not possible iii. Lack of trained physical instructors
			ii.	Evidence on change in BMI limited, small and inconsistent

Peter B. Sullivan, MA, MD, FRCP, FRCPCH

FEEDING, NUTRITION, AND GROWTH

Feeding is essential for survival. Children who cannot or do not eat properly may become unwell and fail to grow.[1] Thus, when feeding becomes problematic it is a source of great concern and anxiety for parents. Such concerns include the amount of food consumed, the rate of weight gain, possetting, restricted food preferences, delay in self-feeding, unacceptable mealtime behaviors, and peculiar food habits.[2]

In addition to its nutritional imperative, the process of feeding is important as a formative influence on the infant's emotional and social development. A major focus of the interaction between an infant and its parents surrounds feeding and thus early feeding experience is important to the psychological development of the child. Feeding is influenced by a wide range of factors including cultural background, parental experience and temperament, and the child's developmental status. This fundamental aspect of life is reflected in the interconnectedness of the words "nutrition," "nourish," "nurture," and "nurse." Feeding thus plays a central role in the life of the child not only in relation to their growth but also in its contribution to their social integration.

Problems with feeding can cause a major disruption to normal growth and development. In addition, they can pose additional complications for the child coping with a chronic disease. To protect the child from the adverse effects of these complications requires great patience and skill on the part of parents and clinicians alike. This chapter aims to describe the development of normal feeding skills and outline the etiology of common feeding problems together with an account of their assessment and management.

Epidemiology

Estimates suggest that up to 25% of infants and young children have some degree of feeding problem[3] although there is no hard epidemiological data on prevalence. Severe feeding problems associated with poor weight gain, such as refusal to eat or vomiting, have been reported to occur in 1%–2% of infants younger than 1 year of age,[4] and 70% of these infants continue to have feeding problems four and six years later.[5,6] Feeding disorders also have been linked to later deficits in cognitive development, behavioral problems, and eating disorders.

There has been remarkably little research on the development of infant feeding problems. Seminal studies by Dahl and colleagues in Sweden on 50 infants meeting strict diagnostic criteria, however, have helped to identify the characteristics and consequences of infant feeding problems.[4–7] Feeding problems in this group had been ongoing for a mean duration of five months. The commonest problems were refusal to eat (56%), colic (18%), and vomiting (16%). The majority (86%) of infants was underweight and 14% were malnourished (>2 SD below mean weight for age). Physical disorder (e.g., gastroesophageal reflux) was present in only 14% but in 6% this was a serious organic disease (e.g., congenital heart disease). Follow up studies at 2 years showed that over a third of the refusal to eat group had a persistent feeding problem.

The Physiology of Feeding

Understanding feeding problems in children rests on a detailed knowledge of oral-motor structure and function, the neurophysiology of feeding as well as child development and behavior. The process of taking in and swallowing food and coordinating this with breathing depends on three linked anatomical and physiological regions: the oral cavity (lips, tongue, and palate), the pharynx and the esophagus.

In a normal co-ordinated nutritive sucking cycle, breathing is intercalated between swallows. In a perfectly co-ordinated cycle suck, swallow and breathing movements are related in a 1 to 1 sequential pattern.[8] These form a rhythmically repetitive unit in which breathing appears to be continuous and uninterrupted. In less well co-ordinated feeding, breathing is always interrupted by swallowing. The co-ordination of the intrinsic muscles of the tongue to produce fully formed rhythmic, rolling movements seems to be in part a productive gestational maturity as premature babies have more poorly co-ordinated tongue movements. The linkage of sucking and swallowing with breathing appears to be achieved

consistently only by infants of more than 37 weeks postconceptional age.[8]

The development of oral-motor skills reflects general neurological maturation and requires the coordination of the movement of at least 31 pairs of striated muscles in the mouth, pharynx, and esophagus by 5 cranial nerves, the brain stem, and the cerebral cortex.[9]

The swallowing process occurs in four phases: oral preparatory, oral, pharyngeal, and esophageal. The first two phases are under voluntary control, with the pharyngeal phase partly voluntary and mostly involuntary, while the esophageal phase is entirely involuntary.

The *oral preparatory phase* involves the processing of food by the lips, teeth, cheeks, and tongue to form a bolus. Good lip seal, a coordinated range of tongue and jaw movements and normal oral sensation are all prerequisites for this phase to proceed without disruption.

In the *oral phase,* the food bolus is propelled towards the pharynx by elevation of the tongue with sequential contact with the hard and soft palates. When the bolus reaches the posterior oral cavity (e.g., soft palate and faucial pillars), the swallow reflex is activated. This sensory stimulus on the posterior oral structures ends the voluntary oral phase and triggers the involuntary pharyngeal phase of swallowing.

During the *pharyngeal phase*, the velum elevates, closing off the nasopharynx, and the pharyngeal constrictors propel the bolus through the faucial pillars to the upper esophageal sphincter (cricopharyngeus) in a peristaltic wave. Concomitantly, the larynx closes, elevates, and is pulled forward by the laryngeal strap muscles. The epiglottis and the aryepiglottic folds, the false vocal folds, and the true vocal folds form three separate levels of laryngeal closure, protecting the airway from penetration by food or liquid. Respiration stops briefly to allow the bolus to move to the relaxed upper esophageal sphincter. The cricopharyngeus muscle serves as the valve at the top of the esophagus. It remains in a fixed state of contraction and only relaxes to allow food or liquid to pass during a swallow.

The pharynx and larynx are richly endowed with chemoreceptors, baroreceptors, and temperature receptors whose purpose is to initiate and modify the swallow. The plethora of these sensitive receptors in the nasopharynx explains the aversive effects on normal swallowing of a noxious stimulus such as the presence of a nasogastric feeding tube.

The *esophageal phase* then begins and involves a continuation of peristaltic transport of the bolus to the stomach. Initiation of the swallowing reflex is often defective in neurologically impaired children and food can then accumulate in the vallecula or pyriform sinuses with

considerable risk of aspiration.

The Normal Development of Feeding Skills

Eating and swallowing are such a natural, subconscious act that it is easy to forget that eating is a learned skill. Unlike breathing, which is similar to feeding in that it is largely subconscious with some element of voluntary control, most of feeding is learned behavior. While the neonate feeding begins as a result of a range of reflexes (gag, phasic bite, tongue protrusion, rooting, suckling, and swallowing reflexes), it later becomes a voluntary act with only the pharyngeal and esophageal parts of the swallow remaining under reflex control. Development of sucking activity is both an inborn conditioned reflex dependent primarily on physiological maturation and it is capable of being strengthened or modified in accordance with learning experiences. Thus, the addition of non-nutritive sucking during gavage feeding, for instance accelerates the organization and efficiency of sucking pattern in premature infants. This has been shown to be associated with a more rapid weight gain [10] and change in gastrointestinal motility[11] during the postnatal period in these infants. Moreover, Morris and colleagues showed that the length of time premature infants needed to reach full enteral feeding was significantly associated with a poorer mental outcome.[12] Infants who reached full enteral feeding at an early age appeared to have a better development outcome despite their gestational age and the severity of respiratory complications.

During the first few months of life, patterns of feeding behavior become established. A typical normal infant will consume around 113 g of milk in 5 minutes and 230 g in 10–15 minutes. Transitional feeding from a predominantly sucking mode of feeding to mature solid food eating begins between 3 and 6 months of age. Growth in the upper digestive tract occurs as the mandible grows downwards and forwards and the hyoid bone and larynx move downwards. The sucking pads are gradually absorbed. All of these changes contribute to an enlargement of the buccal cavity, which allows food to be manipulated between the tongue and the buccal wall. The gradual eruption of teeth allows the infant to progress towards eating harder and lumpier foods. So growth and maturation play a role in feeding development, but learning from experience is also crucial. An important aspect of learning is sensation and sensory feedback. This involves proprioception, touch, pressure, temperature, and taste. Other important factors contributing to learning are gross and fine motor development, the methods of food presentation, and cognitive development. From three to

six months, the process of weaning starts and the early reflex mechanisms that subserve sucking are replaced by more volitional oral movements of the jaw and tongue. This is accompanied by the experience of an increasing range of food tastes and textures. By 6 months of age, an infant is capable of expressing hunger or satiation clearly and from this point is able to play an increasingly participatory role in mealtimes.

Infants and toddlers who take more than 30 minutes to feed are slow feeders and reports of behavioral feeding problems are common in toddlers and are related to slow feeding.[13] Reau demonstrated that toddlers with problematic feeding behaviors e.g., “not always hungry at mealtimes,” “does not always enjoy a feed,” or with strong food preferences at both 6 and 12 months eat more slowly than other toddlers. Thus, asking the mothers of infants and toddlers how long it takes the children to complete a meal should be an essential part of feeding evaluation. Further evaluation should be considered in those cases of reported meal length greater than 30 minutes, especially if lengthy feeding is persistent over time. Evaluation might include oral, motor, and psychosocial evaluation.

Weaning Failure

Weaning is the process whereby an infant becomes accustomed to an intake of solid food in preference to milk. This transitional phase may be associated with disorganization of feeding and infants are often seen to be agitated or unsettled at this stage. During this critical period, infants are vulnerable to develop feeding difficulties. Feeding is a reciprocal process that depends not only on the abilities and characteristics of the infant but also those of their parent. Avoidance by parents of encouraging the infant to make the transition from milk to solids at this time may make the process considerably more difficult at a later time. Similarly, prolonged nasogastric tube feeding or any other noxious stimulus in the oropharynx during this period may be associated with weaning failure.

Etiology of Feeding Disorders

Effective feeding depends on the normality of a wide range of anatomical, physiological, metabolic, and behavioral factors and thus the potential for disease processes to affect feeding is enormous. Table 46-1 itemizes some of the more common causes. It is important to recognize that chronic disease in any organ system in a child can be associated with poor feeding. Thus, anorexia is a consequence of chronic inflammatory diseases such as inflammatory bowel disease and of the metabolic derangement that

accompanies chronic renal failure. Dysphagia secondary to the esophagitis caused by gastroesophageal reflux is a common cause of poor feeding.[14] Suckle and swallow are complex co-ordinated motor actions, which are highly developed in the normal newborn. Because of the functional and anatomical interrelation of these actions with respiration, their impairment assumes great significance. The majority of symptoms and signs of severe dysphagia are respiratory in nature with nasal or laryngeal penetration. Bronchopulmonary dysplasia (BPD), a chronic lung disease of preterm babies with antecedent respiratory distress syndrome, ventilatory barotrauma, and oxygen toxicity is characterized by varying degrees of prolonged oxygen dependency. Infants with BPD can experience significant feeding difficulty, possibly secondary to tachypnea interfering with suck coordination.

TABLE 46-1 Etiology of Feeding Difficulties

Altered appetite
- Abnormal feeding patterns
- Supplemental feedings
- Metabolic disorders
- Inflammatory bowel disease

Diet
- Food allergy
- Inappropriate foods

Dysphagia
- Anatomic:
  - Macroglossia
  - Cleft lip and palate
  - Submucous cleft palate
  - Pierre Robin sequence
  - Laryngeal cleft
  - Tracheoesophageal fistula
  - Esophageal stricture
  - Retropharyngeal mass
  - Vascular ring
  - Foreign body
- Neuromuscular:
  - Prematurity
  - Cerebral palsy
  - Isolated neonatal swallowing dysfunction
  - Bulbar palsy
  - Rett syndrome
  - Infant botulism
  - Muscular dystrophy
  - Pseudo-obstruction
  - Connective tissue disease
  - Repaired tracheoesophageal fistula

Inflammatory:
Viral stomatitis
Candida stomatitis, pharyngitis
Peptic esophagitis (gastroesophageal reflux)
Crohn's Disease
Mucositis (graft-versus-host disease)
Systemic:
Cardiac disease
Pulmonary disease
Behavioral
Poor parent–infant interaction
Autonomy struggles
Picky eater
Delayed introduction of solids
Oral aversion
Conditioned dysphagia
Post-traumatic eating disorder
Vulnerable child
Parental responses

Source: Adapted from Rudolph & Link; Foy et al.; Illingworth.[44–46]

Rommel, characterized the etiology of feeding difficulties in 700 children with severe feeding difficulties and differentiated medical, oral, and behavioral categories.[15] Nearly half of the children had combined medical and oral conditions underlying their feeding difficulties. Oral sensory-based feeding problems appear to be related to past medical interventions. Children with feeding disorders had significant lower birth weight for gestational age and premature babies were over represented. In this study, 86% (603 of 700) of patients had a medical disorder, 61% (427 of 700) had oropharyngeal dysfunction, and 18.1% had a behavioral problem. Of medical diagnoses, a gastrointestinal problem was the most frequent and of these gastroesophageal reflux disease was the most frequent GI condition, diagnosed in 33% (228 of 700 of the total group). An oral feeding problem was diagnosed in 61% of patients and the majority of children with oral feeding problems were less than 2 years of age. The most frequent isolated oral feeding problem was related to sucking and was sensory based.

Oral sensory motor impairment may be present from birth and may often be unrecognized or mislabeled "nonorganic failure to thrive."[16] A common factor underlying such feeding difficulties may be neurophysiological abnormality manifesting as different degrees of oropharyngeal sensorimotor impairment.

Oral-Motor Impairment

Oral-motor impairment may occur as a result of structural lesions (e.g., cleft lip and palate, macroglossia, Pierre-Robin syndrome, esophageal atresia) or functional lesions (e.g., cerebral palsy, bulbar and pseudobulbar palsies, myopathies). In order to attain optimum oral-motor skill, a child must have the ability to move oral and facial structures independently of the rest of the body. Poor control of posture, uncoordinated movements of the upper limbs, lack of independent mobility, visual, hearing and communication problems all contribute to feeding difficulties in disabled children.

Cerebral Palsy

Severe disability is common in the graduates from neonatal intensive care units; the EPICure study group evaluated children who were born at 25 or fewer completed weeks of gestation at the time when they reached a median age of 30 months and 49% were disabled with 23% meeting the criteria for severe disability.[17] Epidemiological studies have shown that these are the children who will encounter feeding difficulties. The North American Growth in Cerebral Palsy Project is a population-based study that evaluated the growth and nutritional status in children with moderate-to-severe cerebral palsy and found the majority (58%) had reported feeding problems.[18] The Oxford Feeding Study examined 440 children with cerebral palsy and feeding problems and found that 89% required assistance with feedings and there were other concerns such as frequent choking (56%), stressful and prolonged feeding (43%) and vomiting (22%).[19] As has been outlined above, to feed effectively, an infant needs to co-ordinate sucking, swallowing, and breathing. Oral motor dysfunction is the primary cause of feeding difficulties in children with disabilities. Reilly et al. (1996) noted that greater than 90% of children with cerebral palsy had clinically significant oral motor dysfunction.[20] Prolonged feeding times, drooling, coughing, and choking with feeds and gagging are all signs of oral motor dysfunction. In one study of 271 children with cerebral palsy, the median length of time caregivers spent feeding per day was 2.5 hours with 28% (72/261) spending more than three hours a day on this activity alone.[19]

NEURODEVELOPMENTAL DISORDERS

Developmental disorders characterized by communication difficulties are

often accompanied by eating problems. Two conditions, autism and Rett syndrome will suffice as examples.

Autism is a developmental disorder characterized by severe deficits in social interaction and communication along with stereotypic behavior patterns. The unusual eating patterns and feeding difficulties of children with autism (which is more common in boys) has long been recognized. They often have an extremely limited food repertoire occasionally with apparent craving for certain foods. Research in this area is limited but in a parent survey of the eating habits of 340 autistic children,[21] two thirds of respondents considered their child to be a “picky” eater. The commonest behavioral problems reported were unwillingness to try new foods, mouthing objects, and rituals surrounding eating. Other problems were licking objects, smelling, and throwing food and pica. 60% of one series of 70 autistic patients exhibited pica.[22]

Rett syndrome may be confused with autism but arises from a mutation in the transcription regulating gene MECP2 on the X chromosome; it occurs almost exclusively in girls. Feeding problems are common in Rett syndrome in which there are characteristic oropharyngeal abnormalities.[23,24] Videofluoroscopic studies of feeding in girls with Rett syndrome have shown reduced movements of the mid and posterior tongue, with premature spillover of food and liquid from the mouth into the pharynx and laryngeal penetration of liquids and solid food during swallowing.[25,26] Air swallowing has also been noted as a problem in these patients.[27]

CONGENITAL HEART DISEASE

Difficulties with feeding are common in children with congenital heart disease (CHD). Both decreased energy intake and increased energy requirements in this group contribute to malnutrition.[28] For most parents feeding of infants and children with CHD poses significant difficulties, is time consuming and associated with considerable anxiety.[29] Maintenance of an adequate caloric intake, in order to achieve sustained growth, is often not possible without nutritional support, often requiring continuous enteral feeding.[30,31]

Cystic Fibrosis

Good nutritional care is an essential part of the management of the child with cystic fibrosis (CF) and is one of the major factors contributing to the

improved longevity of such children. Energy requirements vary but can be in excess of 150% of the daily recommended value for the normal child and this may pose a significant challenge or parents as they try to meet these requirements. A number of studies have highlighted that children with CF are at risk of developing behavior problems during mealtimes.[32,33] Behavioral therapy has been shown by meta-analysis of several studies to be as effective as oral supplementation and enteral and parenteral feeding in improving weight gain in young people with CF.[34]

Type 1 Diabetes

The adolescent years are often characterized by deterioration in the metabolic control of diabetes and it is not uncommon for adolescent girls particularly to be overweight. These changes coincide with the peak period of risk for the development of eating disorders. The commonest abnormality encountered in Engstrom's study of adolescent diabetic girls was binge eating and purging behavior (self-induced vomiting or insulin omission).[35] Diabetics with eating disorders had higher HbA_{1c} concentrations than those without eating disorders.[36] It is not surprising, therefore, that patients with type 1 diabetes and eating disorders have more long-term diabetic complications with an increased prevalence of retinopathy, microalbuminuria, and painful neuropathy when compared with those diabetics without an eating disorder.[37]

BEHAVIORAL DISORDERS

Feeding difficulties are some of the most common behavioral disturbances in young children. An estimated 24% of 2-year-old, 19% of 3–year-old, and 18% of 4-year-old children are reported by their parents as having problems with feeding.[38] These problems can range from nuisance behavior (messy, disruptive mealtime behavior) to total food refusal and life-threatening malnutrition. Any of the organic diseases referred to above can have an additional psychological and behavioral component, which should also be addressed for successful management.

Post-Traumatic Feeding Disorder

Post-traumatic feeding disorder (PTFD) also referred to as conditioned dysphagia, food aversion or food phobia is one type of feeding problem that occurs in infants who refuse to eat and have had distressing experiences involving the mouth, nose, throat, and esophagus.[39] The

prevalence of PTFD is unknown, although it may affect 4% of infants with gastroesophageal reflux who do not have a neurological or craniofacial problem, or a history of esophageal surgery and up to 40% of those who have had esophageal surgery.[40] The increase in PTFD mirrors the increasing number of infants whose survival depends upon advances in medical technology that require invasive procedures (e.g., suctioning, intubation, repeated insertion or removal of nasogastric feeding tubes) involving the oro- and nasopharynx. Such experiences may make the infant associate stimulation in and around the mouth with pain, discomfort or fear and lead to food phobia. With such a phobia, the child experiences intense anxiety if exposed to food and so refuses to eat to avoid the anticipated pain and discomfort. Another proposed mechanism to explain PTFD is visceral hyperalgesia, a neuropathic condition in which prior experience, for example, esophagitis changes sensory nerves in the esophagus so that previously innocuous stimuli, e.g., swallowing liquids or solids, are perceived as painful.

Parental Behavior

It is important to note that there is a clear association between parental behavior and child feeding behavior. Significant associations have been noted between coercive parental behaviors and children's food refusal and noncompliance.[41] In the study by Sanders and colleagues[41], feeding-disordered children engaged in higher levels of disruptive mealtime behavior (food refusal, noncompliance, complaining, oppositional behavior, and playing with food) and lower levels of chewing during mealtime. There were several significant age effects, with younger children (under age 3) engaging in more vomiting and less aversive demanding and verbalizations. Parents of feeding-disordered children were more negative and coercive in their feeding practices and engaged in higher levels of aversive instruction giving, aversive prompting, and negative eating related comments than parents of non-problem eaters.[41] Dahl et al. (1986) found that four factors were highly significant in predicting feeding problems in infants (1) feeding problems in the parents during their own infancy, (2) great anxiety experienced by the mother during pregnancy, (3) breastfeeding problems experienced by the mother, and (4) ill health in the mother. These studies provide support for the recommendation that evaluation of the feeding relationship should be an essential part of the diagnostic study of any child with feeding problems and for treatment methods that directly alter parents' feeding practices.

ASSESSMENT

Clinical History

A multidisciplinary team (MDT) approach offers the best way to diagnose the cause of the feeding problem and to assess the needs of the child. The members of this MDT typically comprise a pediatrician, a speech and language therapist, a dietitian, a psychologist, and an occupational therapist. Following assessment the MDT together with the parents can then formulate a management plan.

Southall and Martin[47] have produced clinical practice toolkits for assessment, problem formulation, and intervention with a child with feeding problems, which can be downloaded from http://www.radcliffehealth.com/shop/feeding-problems-children-practical-guide-0

A comprehensive clinical history is of particular value in the evaluation of infant dysphagia. As in other areas of clinical work, familiarity with the mechanisms and patterns of feeding disability results in a more perceptive enquiry and more meaningful description. The clinical history may identify the cause of the feeding difficulty and may also reveal associated conditions such as a history of pneumonia raising the suspicion of recurrent aspiration.

A detailed feeding history in indispensable and includes details of the child's feeding since birth, any changes of formula, introduction of solids, current diet, textures, feeding position, route and time of administration of feeds, and meal duration. Careful inquiry into the details of any food aversions and allergies is essential. In conjunction with the feeding history, a dietetic assessment is important to determine whether the caloric intake is adequate. Psychological assessment will help to identify behavioral and parental factors (e.g., family relationship issues, emotional problems) that contribute to the feeding disorder.

Examination

An important component of the detailed physical examination is observation of a feeding episode, as this will often provide significant insight into the underlying feeding problem. The level of interaction between the child and parent, verbal and nonverbal communications, the child's responses to offered foods, including disruptive behaviors such as spitting or turning the head away all give invaluable information. In conjunction with the dietitian who undertakes formal anthropometric analysis of nutritional status, the child's growth should be plotted on

appropriate reference charts. Feeding problems may be the harbinger of a serious underlying neurodevelopmental or metabolic problem and so such children need careful developmental assessment. Any suspicion of significant developmental delay indicates the need for more formal assessment by a neurodisability pediatrician.

Investigations

A careful developmental medical and feeding history, together with physical examination provides clues to the diagnosis and guides the selection of further investigations.

Perhaps the most relevant of these in the content of feeding problems is a videofluoroscopic swallowing study, which can assist in the identification of the conditions for safe swallowing and adequate protection of the airway. It is important to appreciate that not all aspiration or penetration identified by video fluoroscopy is, in fact, clinically significant in terms of the risk of chronic lung disease.[42]

Further details of the investigation and management of dysphagia (impaired swallowing) in children can be found in the excellent review by Anna Dusick.[43]

Management

Successful clinical management of infants with feeding difficulties depends upon the experience and skills of the multidisciplinary health care team and, crucially, the mother. It is impossible to generalize about best procedures or feeding routines apart from those few diagnoses (e.g., cleft lip and palate) where specific therapy is indicated.

Feeding problems that begin in infancy may persist and can result in reduced growth in height and weight. In some children, early oral motor dysfunction leads to slow and difficult feeding and the development of feeding aversion. Accordingly, it is observed in some older patients without current oral motor problems that early oral motor dysfunction which has resolved has led to acquired dysfunctional feeding behavior and poor nutritional intake. In such patients, early intervention to reduce oral motor dysfunction and consequent behavioral reactions might prevent growth compromise, long-standing behavioral problems and family discord.

The biomedical model of etiology proposes anatomical, oral-motor, or subtle sensory deficits as an explanation for feeding disorders. An appreciation of the additional insights provided by a biopsychosocial

model of causation[38] is necessary for a fuller understanding of this complex problem. Such an appreciation is essential to the development of effective management and intervention strategies for children with feeding disorders.

Reau and colleagues suggest that a combination of factors such as family dysfunction or maternal stress sometimes results in a preoccupied mother who is unaware of her infant's eating distress stemming from an organic problem.[13] In other cases, the mother is aware but is unsure what to do about it and the pediatrician may not think of oral motor dysfunction. As discussed above, PTFD is characterized by refusal of specific "feared" textures, for example, formula that has caused dyspepsia, lumpy foods that have made the infant gag. Other symptoms include acceptance of the "feared" food only when in a drowsy state (e.g., "dream feeding"), lack of awareness of hunger and thirst, and anxious anticipation of meal times as when events associated with being fed such as the site of food, feeding chair, or bottle trigger symptoms such as crying, gagging, coughing, retching, vomiting, and escape behavior such as squirming or crawling away. Four specific feeding behaviors (not chewing, sucking, or moving the food placed in the mouth for more than five seconds, passively refusing to swallow once the food was placed in the mouth, spitting out, and retching) exhibited by infants with PTFD will predict treatment outcome in most cases. These could be viewed as "bad habits" learnt by infants to avoid swallowing that need to be extinguished.

From a psychological perspective, feeding behaviors may result from either classical or operant conditioning and the distinction between these two has important clinical implications. Feeding behaviors resulting from classical conditioning (or stimulus response learning) are minimally influenced by consequences (e.g., punishment or reward) after the behaviors occur. For instance, withdrawing attention when an infant refuses food will not extinguish this behavior if it has been acquired by classic conditioning. Phobic responses, such as those seen in PTFD, are classically conditioned. Classical conditioning methods of treatment, therefore, are likely to be the most effective to help infants overcome their fear of swallowing or food phobia. Two commonly used treatment methods to extinguish behaviors resulting from classical conditioning are systematic desensitization and flooding.

Systematic desensitization provides slow, gradual exposure to the fear, for example, food with the infant largely controlling the rate and intensity of exposure. There is no evidence to support the efficacy of desensitization in the treatment of PTFD.

The behavioral technique that is believed to most helpful to treat PTFD is flooding.[3] Flooding provides rapid and intense exposure to the feared stimulus, for example, food with the therapist largely controlling the rate and intensity of exposure and providing active assistance with anxiety control. In the first few sessions, this technique is associated with much distress and fear and crying but with perseverance real improvement can be observed in days or weeks.

Feeding behaviors that result from operant conditioning are dependent on stimuli that precede the behaviors and on the responses that followed the behaviors. For example, if an infant is asked to swallow food placed in their mouth and the feeder responds with praise for swallowing then this behavior is reinforced and the infant is likely to comply the next time they are asked to swallow. Thus, the maintenance or extinction of specific mealtime behaviors learnt through operant conditioning will depend on the feeders' response to the behavior. Operant conditioning techniques range from contingency management, for example, extinction, timeout, positive reinforcement, to punishment, or aversive techniques such as bitter tastes. In PTFD, contingency management alone is particularly unhelpful, perhaps because infants with PTFD are more afraid of swallowing than eager to receive praise for swallowing.

CONCLUSION

Although common and affecting up to a quarter of normal small children, feeding disorders are often temporary. They are, however, very heterogeneous in manifestation including food refusal, dysphagia, hyperphagia, and pica. Feeding disorders arise from multiple etiologies but in general are based on three groups of children; those who are otherwise healthy, those with digestive disorders (especially gastroesophageal reflux) and those with neurological impairment. Special cases include children with congenital heart lesions, CF, type 1 diabetes, cancer, and developmental disorders (e.g., Rett syndrome and autism).

Multidisciplinary assessment and management is essential to a successful outcome. Both biomedical and biopsychosocial models of health care can contribute insights to help address underlying organic pathologies, support nutritional status and modify aberrant feeding behaviors.

Failure-to-Thrive: Growth Failure in the Outpatient Setting

47

Jennifer A. Woo Baidal, MD, MPH Susanna Y. Huh, MD, MPH

BACKGROUND AND DEFINITIONS

Although the term "failure to thrive" (FTT) has been in use for over a century, a consensus definition does not exist.[1–3] FTT is not a diagnosis with a single etiology, but rather a description of an abnormal growth pattern reflecting failure to grow at an expected rate consistent with growth standards.[4] Terms such as growth failure, inadequate growth, and weight faltering have begun to replace the use of the term FTT, which may have negative connotations.

Specific definitions for growth failure are variable,[5] but there is general consensus that the definition should be based on anthropometric measurements.[3] A common static definition of growth failure based on attained growth is sex-specific weight-for-age or weight-for-length less than the 2 (3rd percentile) or more than 2 standard deviations below the mean for a reference population (z-score < −2). Other published cutoffs used to define failure-to-thrive include the 5th or 10th percentiles of weight-for-age or weight-for-height, or height-for-age less than the 3rd or 5th percentiles.[3] Optimally, measurements should be obtained on two or more occasions to support a definition of growth failure.

The World Health Organization (WHO) recommends expressing anthropometric measures in z-scores at both the individual and population level.[6] The weight-for-age z-score can be calculated using the following formula:

weight-for-age z-score = [actual weight - median weight] /standard deviation

where "z-score" refers to age- and sex-specific standard deviation of weight, and "median weight" refers to the median value for age and sex.[7] Online calculators and some electronic medical record software programs can assist in calculating z-scores, such as those found at www.statcoder.com. The use of z-scores allows for a more precise description of a child's growth compared to the use of percentiles. For example, a child whose weight-for-age plots "below the 3rd percentile" could have a weight-for-age z-score of either −2.1 or −3.5, encompassing a wide range of severity.[7] For a child with growth failure, the use of z-scores also allows for more precise quantitative longitudinal monitoring of a child's growth than centiles. A child whose weight-for-age improves from a z-score of −2.9 to −2.2 would have a weight-for-age below the 3rd percentile at each time point, masking the progress in growth that has occurred.

A dynamic definition of growth failure is based on decreased growth velocity, defined as weight-for-age or height-for-age curves that have crossed downward more than two major percentile lines (such as 5th, 10th, 25th, 50th, 75th, 90th, and 95th) after having previously achieved a stable growth pattern. Defining a stable pattern can be difficult, particularly in infancy when weight percentiles commonly fluctuate, as discussed in further detail below. The phenomenon of regression to the mean describes the tendency of large infants to cross percentiles downward and small infants to cross percentiles upward toward the mean of a reference population.[8] To account for regression to the mean, some research studies have used "conditional weight gain" <= 5th percentile to define growth failure, which compares an infant's weight gain with weight gain of other infants of the same sex and initial weight; this definition is difficult to apply to clinical practice.

The proximate cause of the majority of growth failure cases is malnutrition or undernutrition.[9] The terms malnutrition or undernutrition are often used interchangeably with growth failure, although the terms are not synonymous. Waterlow[10] proposed criteria for distinguishing between

acute and chronic undernutrition with the terms wasting and stunting. Wasting is defined as a weight-for-height <= 90% of the median and represents acute malnutrition. Stunting is defined as a length-for-age or height-for-age that is 90% or less of the median and represents chronic malnutrition. Table 47-1 shows the Waterlow classification for categorizing malnutrition.[10] To calculate the percentage of the median, the following formula can be used:

$$[\text{Actual weight}/\text{median weight}] \times 100 = \%\ \text{median}$$

where median weight is the median value for age and sex. Determining the severity and chronicity of malnutrition can help direct intervention as described below.

EPIDEMIOLOGY

The prevalence of pediatric growth failure is difficult to estimate for several reasons. The lack of a consistently used definition for growth failure impedes comparison of prevalence estimates across studies. Several other factors can interfere with nationally representative information on the prevalence of growth failure in infants, including sample and selection bias.[11] When interpreting national prevalence estimates, it is important to note that estimates of growth failure are equivalent to estimates of undernutrition; growth failure prevalence estimates frequently include low-birth-weight infants, who may account for 20%–40% of low-weight or short children.[4,12]

TABLE 47-1 Waterlow Criteria for Categorizing Type and Chronicity of Malnutrition

Type of Malnutrition	Acute (Weight for Height) (% of Median)	Chronic (Height for Age) (% of Median)
Mild	80–90	90–95
Moderate	70–80	85–90
Severe	<70	<85

Acute malnutrition (abnormal weight-for-height) is termed “wasting” and chronic malnutrition (abnormal height-for-age) is termed “stunting.”

Source: Adapted from Waterlow et al.[6]

Mei and colleagues studied nationally representative data from the National Health and Nutrition Surveys (NHANES) 1999–2004 to compare the prevalence of underweight using three cut-off points on the WHO and CDC weight-for-age growth curves.[13] Mei found that approximately 2% of infants were underweight when a cut-off of 2.3rd percentile, (−2 z-score) on WHO charts was used. When the cutoff was increased to the 5th percentile, the prevalence of underweight among infants under age 2 years was 3.8% on WHO charts and 6.8% on CDC charts. Similar trends were seen for weight-for-age estimates among older children.[13] Fewer US children are expected to be diagnosed with underweight when weight and length are plotted on WHO charts.[14] Figure 47-1 illustrates changes in the estimated prevalence of low weight-for-age according to different charts and cut-off values.

Recent epidemiologic evidence suggests that the number of underweight children in the United States has declined over the past three decades. Among children and adolescents in NHANES, the prevalence of underweight defined as BMI < 5th percentile declined from 5.1% in 1971–1974 to 3.5% in 2007–2010.[15] Among children aged 2–5 years, underweight decreased from 5.3% to 3.4% during the same time period.[15] These data excluded infants under the age of 24 months, the most vulnerable age group for low weight-for-age and low weight-for-length. The prevalence of underweight may be higher among specific subgroups. Frank and Zeisel reported in 1988 that an estimated 10% of low-income children in the United States were undernourished.[16]

Globally, an estimated 16% of children under 5 years of age were underweight (weight-for-age z-score < −2) in 2010 in the WHO Global Database on Child Growth and Malnutrition.[17] The prevalence of childhood underweight was 1.5% in developed nations and 17.5% in developing nations.[17]

RISK FACTORS

A newer understanding of the complex interactions between multiple factors that contribute to a child's nutritional status is replacing the previous perspective that growth failure results from either "organic" or "nonorganic" causes. Organic causes of growth failure refer to chronic medical disorders that interfere with growth, such as malabsorption, genetic syndromes, endocrine disorders, and neurologic dysfunction.[4] Nonorganic growth failure has traditionally been defined as a diagnosis of

exclusion, to label growth failure in a child when a medical condition is not identified.[4] However, this dichotomous approach does not recognize that children with growth failure commonly have more than one physiologic and psychosocial factor contributing to their undernutrition.[2,18] Further, this approach emphasizes the potential of a "missed" medical diagnosis and can lead to extensive invasive and unnecessary medical evaluation. In some series, as many as 90%–95% of children with growth failure had no underlying medical condition.[2,18] Growth failure can result from a "layering of risks," where multiple risk factors interact to cause growth failure in an infant who might have otherwise grown normally if only a single disease or a single psychosocial risk factor existed.[4]

Perinatal Risk Factors

Perinatal factors, including preterm birth and birth weight, genetic and developmental conditions, or environmental exposures can all predispose a child to growth failure. Infant preterm birth, including late preterm birth,[19] is an important risk factor for growth failure. Compared to term counterparts, infants who were both low birth weight (≤2500 g) and preterm (≤37 weeks) have been found to have smaller mean lengths, weights, and head circumferences in the first 3 years of life, even after correction for gestational age.[20,21] Preterm infants can have anthropometric measures plotted on curves developed for preterm infants until they achieve a postconceptual age of 40 weeks;[19,22,23] thereafter their measurements can be plotted on standard growth charts.

Both preterm and term infants who are born small for gestational age (SGA) are at risk for growth failure. Small for gestational age is usually defined as birth weight and/or length 2 standard deviations smaller than the mean for gestational age and sex in a reference population (z-score < −2).[24,25] Historically, the terms small for gestational age and intrauterine growth restriction (IUGR) have been used interchangeably, but the term IUGR should be reserved for infants with documented aberrant prenatal fetal dimensions[24]; the most common definition of IUGR is sonographically estimated fetal weight below the 10th percentile.[26] Term infants born SGA have growth failure that appears to be in part related to familial short stature. Data from the National Collaborative Perinatal Project, an 8-center US study of perinatal risk factors and growth and development in term infants (>=37 weeks gestation), reported that mean height of mothers of infants born SGA (defined as birth weight <=2500 g)

was 2 cm shorter than for mothers of infants without SGA.[27] Compared to preterm infants born appropriate for gestational age, preterm infants born SGA are at higher risk of growth failure in early childhood.[28]

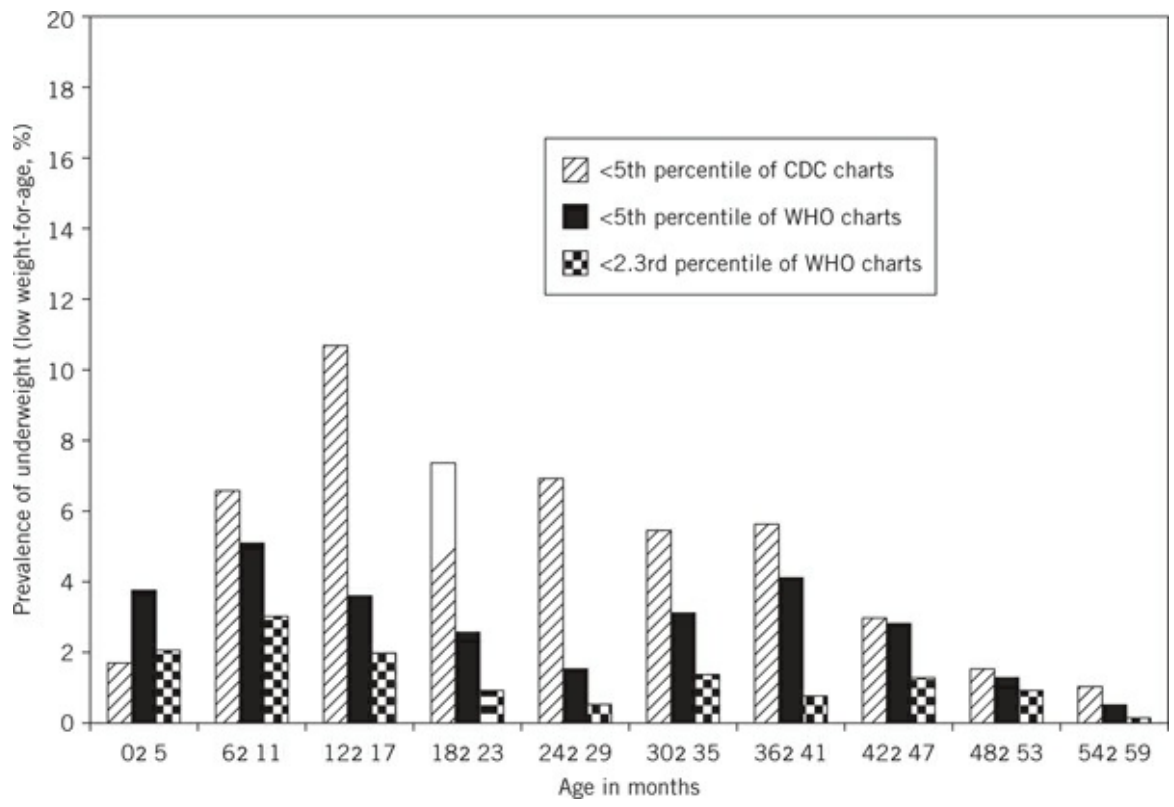

Figure 47-1 Comparison of prevalence of underweight (low weight-for-age) based on the CDC 2000 and WHO 2006 growth charts, NHANES, NHANES 1999–2004 for children aged 0–59 months. Reprinted with permission from the *Journal of Pediatrics*; Mei et al.[13]

Several reasons for in utero growth failure exist, including environmental exposures (maternal smoking, undernutrition, drug or toxin exposure), maternal medical complications, placental abnormalities, and fetal problems (chromosomal abnormalities, inborn errors of metabolism, or intrauterine infections).[10,24] Traditionally, growth symmetry has been thought to reflect the origins of in utero growth failure and prognosis for future somatic growth. Symmetric IUGR (proportional weight, height, and head circumference) was classically thought to result from undernutrition or other processes affecting the 1st or 2nd trimester, whereas asymmetric IUGR (disproportionately affected weight) was thought to result from

undernutrition or insults occurring during the 3rd trimester.[24] Recent data show that both symmetric and asymmetric IUGR can arise from the early second trimester.[29] Prenatal ultrasound measures of fetal growth parameters do not predict birth anthropometric measures well, perhaps due to in utero crossing of percentiles.[30] Villar et al.[31] suggested that infants with symmetric IUGR are less likely to respond to nutritional intervention, while those with disproportionately affected weight are more likely to have experienced in utero malnutrition and respond to nutritional intervention after birth. However, other data show that preterm infants born with either symmetric or asymmetric SGA have limited catch-up growth through 3 years of age.[32]

Medical Risk Factors

Congenital and chronic medical conditions can lead to poor weight gain through a variety of mechanisms.[33] Medical risk factors for the development of growth failure can be categorized as inadequate caloric intake, malabsorption, excessive caloric expenditure, and/or defective utilization of nutrients (Table 47-2). We briefly outline some common medical risk factors in this section; a detailed review of the many medical conditions associated with growth failure can be found elsewhere in this textbook.

Neurologic conditions, particularly cerebral palsy, are often associated with abnormal growth and nutrition in both preterm and term infants.[34–39] In addition to inadequate intake, other risk factors for growth failure in neurologically impaired children include oral motor dysfunction; increased nutrient losses due to emesis or spillage; and excessive energy expenditure related to hypertonia or movement disorders.[40] Thirty to forty percent of children with cerebral palsy are estimated to have feeding difficulties,[41,42] which can result in part from impaired central and enteric nervous system function.[43] Contractures or scoliosis can make measurement and interpretation of linear growth challenging in children with cerebral palsy; alternative measures such as upper arm and lower leg lengths can be plotted on available growth curves.[37,39] These measurements have been found to correlate with triceps skinfold thickness and mean arm circumference.[37] Triceps skinfold thickness can be helpful in the nutritional assessment in children with cerebral palsy, with values under the 10th percentile for age and sex indicating the need for additional assessment of nutritional and growth status.[36]

TABLE 47-2 Etiologies of Growth Failure

Mechanism	Examples of Associated Condition
Inadequate caloric intake	Reduced appetite Inappropriate dietary intake Improper formula mixing Excessive fruit juice consumption Mechanical feeding problems (Oral motor deficits) Congenital anomalies (Cleft lip or palate) Impaired swallowing (Dysphagia) Altered mental status Behavioral feeding disorders Disordered feeding techniques Infantile anorexia Sensory-based food aversions Inadequate food supply Insufficient breastmilk supply Neglect or abuse Poverty
Inadequate absorption	Gastrointestinal disease Vomiting Mucosal abnormality (Celiac disease, enzyme deficiency) Intestinal failure Pancreatic insufficiency (Shwachman-Diamond syndrome, cystic fibrosis) Chronic liver disease with cholestasis
Excessive energy expenditure	Hypertonia Chronic disease Congenital or acquired heart disease Chronic pulmonary disease Endocrine abnormalities Chronic or recurrent infections/fevers HIV or other immunodeficiency Malignancy (diencephalic syndrome)
Defective utilization	Genetic conditions Trisomies 21, 18, 13 Metabolic disorders

Source: Adapted from Gahagan; Markowitz et al.[4,7]

Estimation of energy needs in children with neurologic conditions can be a challenge. Estimation of energy needs using age-based EER/RDA or standard equations can result in excessive caloric intake, especially among nonambulatory children.[44–46] Table 47-3 lists suggested energy requirements based on calorie per centimeter of height for children with developmental delay.[47] Children with cerebral palsy may benefit from use

of indirect calorimetry to precisely estimate energy requirements.[46]

Children with cleft lip and palate have been considered to be at risk for undernutrition and growth failure, possibly related to an inadequate seal around the nipple, inadequate generation of negative sucking pressure, frequent respiratory and ear infections, and psychosocial factors.[48] In one cross-sectional study of 881 Brazilian children with cleft lip and/or palate, 20%–30% were found to have weight or height less than the 10th percentile for age during the first 2 years of life.[49] Other longitudinal studies have not shown significant FTT in children with nonsyndromic cleft lip and/or cleft palate through the first 2–5 years of life.[48,50] Children with cleft lip or palate as part of a syndrome may have a greater risk of growth failure than children with isolated cleft lip or palate.[48] Associated oral-motor dysfunction may lead to the need for special nipples, feeding instructions, or enteral tube feeding. A 2011 Cochrane review found limited data suggesting that breastfeeding may be associated with higher weight at six weeks postsurgery, as compared with spoon feeding, but no evidence that any particular bottle type was associated with improved infant growth.[51]

Difficulty with chewing, sucking, or swallowing adequate amounts of food may result in inadequate caloric intake leading to growth failure. Dysphagia can be defined broadly as a mechanical difficulty with swallowing. Oropharyngeal dysphagia can be defined as "a dysfunction of the pharyngeal phase of swallowing that allows laryngeal penetration and tracheal aspiration of small volumes of solid food or liquids."[52] Anatomic (e.g., Laryngeal cleft, tonsillar hypertrophy), physiologic (e.g., Eosinophilic esophagitis, food allergy, sinonasal secretions), and neuromuscular etiologies (e.g., Type I Chiari malformation) may lead to oropharyngeal dysphagia, in neurologically intact children[52] as well as children with genetic syndromes.[53] Chapter 48 discusses the causes and treatment of dysphagia and feeding difficulties in more depth.

Recent data link sleep problems in early childhood to feeding difficulties. In a case-control study, parents of children with feeding disorders reported shorter child sleep duration and delayed sleep time, compared with controls.[54] Sleep-disordered breathing in children, which is primarily related to adenotonsillar hypertrophy, has been associated with growth failure. A systematic review and meta-analysis found that child height and weight, and IGF-1 and IGFBP-3 significantly increased after adenotonsillectomy.[55]

Psychosocial Risk Factors

Poverty is the single greatest risk factor for undernutrition worldwide.[56,57] In low and middle-income countries, low weight, height, and BMI are clearly associated with short adult height and other adverse outcomes. In some developed nations such as the UK, prospective cohort studies have not found a clear association between socioeconomic status and poor conditional weight gain (<5th percentile) during the first 9 months of life, perhaps because of an adequate social safety net and study cohorts with a greater proportion of affluent participants than the general population.[8,58] In the United States, poverty remains a key social risk factor for childhood malnutrition. In 2011, almost 15% of US households reported food insecurity, defined as "uncertain of having, or unable to acquire, enough good to meet the needs of all their members because they had insufficient money or other resources for food."[59] Higher rates of food insecurity were reported in households with children under 6 years old (21%) and Black (25%), Hispanic (26%), and low-income households (35%).[59] Federal supplemental nutrition assistance programs appear to help alleviate food insecurity and improve nutrient intake; however, the low level of benefits —in 2006, SNAP was estimated to provide $1.40 per participant per meal —can mean that even concurrent participation in multiple programs may not adequately alleviate food insecurity.[9] Compared with infants receiving benefits, US infants < 12 months old who were eligible for but not receiving benefits from the Special Supplemental Program for Women, Infants, and Children (WIC) exhibited lower mean weight-for-age z-score (−0.23 vs. 0.009) and shorter stature (length-for-age z-score −0.23 vs. −0.02).[60] Housing insecurity has also been associated with lower weight-for-age z-scores.[61]

TABLE 47-3 Estimated Energy Needs for Developmentally Delayed Children

	Daily Caloric Recommendation
Ambulatory, ages 5–12 y	13.9 kcal/cm height
Nonambulatory, ages 5–12 y	11.1 kcal/cm height
Cerebral palsy with decreased levels of activity	10 kcal/cm height
Cerebral palsy with increased levels of activity	15 kcal/cm height
Athetoid cerebral palsy,	Up to 6000 kcal daily

adolescence	
Down syndrome, boys ages 5–12 y	16.1 kcal/cm height
Down syndrome, girls ages 5–12 year	14.3 kcal/cm height
Myelomeningocele	Approximately RDA for age may need as little as 7 kcal/cm height

Source: Adapted from Pemberton et al.[47]

Parental stress can impact a child's growth. Cross-sectional evidence has demonstrated a link between a mother's own experience of abuse as a child, and offspring growth failure. One case-control study of infants with growth failure found that 66% of mothers with infants experiencing growth failure had been abused in childhood, compared to 26% of mothers with children without growth failure.[62] A prospective study that recruited low-income mothers found that maternal report of experience of childhood abuse and unhappiness during pregnancy correlated with subsequent child growth failure through the age of 12 months.[63] Negative interactions between the child's mother and father, such as frequent separations and arguments, were also related to child growth failure.[63] Recent reviews report that maternal depression during an infant's first year appears to be a risk factor for poor growth through the first 2 years of life.[64,65] While the mechanisms underlying the association between maternal depression and child growth are not clear, maternal depression has been associated with suboptimal parenting behaviors, child behavioral difficulties and child developmental delays,[66,67] which themselves may be risk factors for underweight. Maternal anxiety and lack of maternal attachment have also been associated with growth failure.[68–70]

A systematic review of studies from developing countries found that maternal depression was associated with higher odds of underweight (usually defined as weight-for-age z-score <−2) and stunting (usually defined as height-for-age z-score <−2); the OR for underweight strengthened from 1.5 to 2.2 when the meta-analysis was restricted to longitudinal cohort studies.[65] Studies from developed countries also show that maternal depression is associated with lower child weight and height. In a U.K. case-control study, children ≤ 2 years of age with growth - faltering had mothers with higher rates of postnatal depression (OR 1.7, 95% CI 1.2–2.5) and anxiety (OR 2.1, 95% CI 1.3–3.3) than mothers of matched control children.[67] In a study of 181 U.S. Latina mothers, those with depressive symptoms both prenatally and at 4–6 weeks postpartum

were more likely to have children who were underweight (weight-for-age <5th percentile) in the first 2 years of life.[68] The nationally representative US Early Childhood Longitudinal study showed that children of mothers with moderate/severe depressive symptoms at 9 months postpartum had 1.5 higher odds (95% CI 1.03–2.13) of being ≤10 percentile in height-for-age at 5 years[71]; there was no increase in the odds of low weight-for-height. One cross-sectional U.S. study did not show an association between a positive 3-item maternal depression screen and odds of low child growth (weight-for-age <5th percentile or weight-for-height <10th percentile), among children aged 0–36 months old seen in urban hospital clinics or emergency departments.[66] Together these studies suggest that maternal depression prenatally or in the first postnatal year, but not later in childhood, may affect child growth during infancy and beyond, but more prospective data are needed.

Disturbances in feeding behaviors are associated with growth failure,[69,70,72–75] but in many studies it can be difficult to ascertain whether disruptive feeding behaviors are a cause or a consequence of growth failure. Severe food refusal resulting in markedly reduced intake of either solids or beverages can be an obvious cause of growth failure. Examples of behaviors exhibited by children with feeding disorders include food refusal, disruptive mealtime behavior, and food preferences limited to specific brands, types or textures.[76] Successful development of child feeding skills and behaviors depends on multiple factors, including: medical, physical, developmental and temperamental characteristics of the caregiver and child; psychosocial stressors; and positive caregiver-child interactions.[77]

There is no universally accepted classification system for feeding disorders. The central importance of the parent-child relationship to the development of feeding disorders led one group of experts to propose multiaxial diagnostic criteria for a “Feeding Disorder Between Parent and Child.”[77] Nicholls[78] described several common clinical presentations of childhood feeding disorders, including pica, rumination disorder, selective eating, food avoidance emotional disorder, food phobias, functional dysphagia, and food refusal. The Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood (DC:0–3R), based on criteria developed by Chatoor,[79] defines “feeding behavior disorder” as difficulty in regulating feeding in response to physiological feelings of hunger or fullness.[80] The DC:0–3R also defines six subtypes of this disorder. The “Avoidant restrictive food intake

disorder" defined in DSM-5 replaces "feeding disorder of infancy and childhood" in DSM-4.[81] The three disorder subtypes under "Avoidant/restrictive food intake disorder" in DSM-5 mirror the DC:0-3R classification. Table 47-4[79–82] summarizes the DC:0–3R and DSM-5 classifications of feeding disorders.

Aberrant family perceptions of healthy eating can lead to parental restriction of a child's macro- or micronutrient intake, resulting in growth failure. Replacement of breast milk or formula with developmentally-inappropriate beverages, such as soy milk or rice milk, in order to align with family dietary practices, has been reported to lead to severe growth failure.[83] Several published cases of growth failure have been associated with prolonged duration of exclusive breastfeeding with delayed introduction of solid foods beyond 6–8 months of age.[84,85] Parental fear of obesity or cardiovascular disease can lead to suboptimal caloric intake or a diet with insufficient fat content that leads to poor growth.[86] Excessive fruit juice intake can lead to poor nutrition. Some fruit juices can lead to chronic diarrhea, as well as displacement of nutritionally-rich foods in the diet.[87,88] One case series of eight children with growth failure showed that reduction of juice intake was associated with improved weight gain.[89]

TABLE 47-4 Classification of Feeding Disorders Among Infant and Children

Diagnostic Classification of Developmental Disorders of Infancy and Early Childhood				DSM-5
Disorder Type	**Age of onset**	**Infant/Child Features**	**Treatment**	**Avoidant /Restrictive Food Intake Disorder**
Feeding Disorder of State Regulation	Age 0–6 mo	Disordered development of behavioral regulation Difficulty reaching and maintaining calm alertness for feedings or hard to awaken for feedings	Reduce stimulation at feedings if irritable Gentle stimulation prior to feedings if hard to awaken Treat parental depression, anxiety	Not included
Feeding Disorder of Caregiver-	Age 0–12 months	Limited emotional nurturing Reduced social	Intensive feeding intervention (multidisciplinary	Not included

Reciprocity		reciprocity at feedings. Caregiver unaware of or denies problems	clinic, home-based intervention, or hospitalization) Family therapy on nurturing emotional and physical development of child	
Infantile Anorexia	Ages 6 mo–3 y	Feeding refusal and poor hunger drive Refuses adequate amounts of food at least 1 month Behavioral difficulties (e.g., throw food, refuse to open mouth)	Parental education on separation of feeding roles, limit-setting Structured meals and snacks Foster self-feeding and eliminate distractions or coercive feeding	Individuals who do not eat enough or show little interest in feeding
Sensory Food Aversions	Age 0–3 y	Association of specific food characteristics with aversive response. Consistent refusal of specific foods or beverages based on taste, texture, temperature, or smell for at least 1 mo. Sensory difficulties (gag, vomit, or grimace with food)	Introduce variety of foods but avoid foods eliciting strong aversive reactions Model behavior (parents, peer feeding group) Supplemental macro- and micronutrients if needed Behavioral therapy	Individuals who only accept a limited diet in relation to sensory features
Post-Traumatic Feeding Disorder	Any age	Traumatic event involving oropharynx or gastrointestinal tract triggers intense and anticipatory fear of feeding Severe, consistent refusal of solids and/or beverages following traumatic event Child distress at sight of food or food reminders	Behavioral therapy (extinction or desensitization) Enteral feeding support	Individuals whose food refusal is related to aversive experience
Feeding disorder associated with a concurrent medical	Any age	Medical condition believed to cause distress Initiates feeding but becomes distressed or refuses to continue	Treat underlying medical condition Behavioral therapy	Exclusion criterion

condition	feeding

Food allergy is estimated to affect 6%–8% of children at some point during childhood, with as many as 20% of children on an elimination diet due to perceived food allergy.[90] Unnecessary dietary restriction due to perceived food allergies – sometimes resulting from the use of alternative, non-validated allergy tests – can result in growth failure and micronutrient deficiencies.[91] In 2010, Tierney et al.[92] reviewed nineteen reports of severe dietary restriction, usually related to parental concern for allergic or other adverse reactions to specific foods, associated with kwashiorkor in US infants.

Over 12 million children are adopted by North American families from countries around the world each year, and these children commonly experience poor growth.[93] The degree of growth failure is proportional to the duration of time spent in an orphanage.[93] Growth failure among adopted children may be related to poor nutritional intake related to psychosocial deprivation, but stressors such as relocation, language barriers, extended periods in orphanages, or witnessing war and other acts of violence may also contribute to poor growth.[94–96]

Childhood neglect is a possible, but uncommon, contributor to growth failure.[62,97,98] Mediators of this link can include food withholding or intentional starvation.[99,100] Intentional starvation in infants and children has dire consequences. In one case series of 12 criminally prosecuted cases of intentional infant and child starvation, 10 of the children had severe wasting and stunting, and 2 had mild or moderate wasting.[100] Half of the infants and children died shortly before or after being assessed by medical or law enforcement personnel.[100] Although neglect or abuse are rarely the cause of growth failure, the severity of the consequences in cases of starvation underscore the need for providers to screen for serious social and psychological family problems.

Medical child abuse is defined as “unnecessary and harmful or potentially harmful medical care at the instigation of a caregiver,” and includes the commonly used term, Munchausen syndrome by proxy.[101] Although medical child abuse is rare, with incidence estimated at approximately 2 in 100,000 infants < 1 year old,[102] up to 25% of published reports of medical child abuse involved child anorexia or growth failure.[103] Mash et al.[103] compared characteristics of 17 cases of suspected or confirmed medical child abuse with 68 controls among children

evaluated in a pediatric gastroenterology clinic for failure-to-thrive over a 10-year period. They identified several risk indicators which can be used to screen for medical child abuse in cases of failure-to-thrive: involvement of five or more organs; absence of a serious congenital anomaly or -confirmed genetic disorder; five or more reported allergies; and parental refusal of services from a multidisciplinary feeding team.[103]

GROWTH CHARTS FOR SCREENING AND DIAGNOSIS

One goal of routine health supervision is to monitor the growth pattern of a child over time. Serial measurements of weight and length/height plotted on growth charts allow pediatricians to assess a child's growth trajectory and detect abnormal growth patterns. To appropriately screen for and diagnose growth abnormalities, infants and children should be weighed with minimal clothing on scales that measure to a precision of 100 grams.[7] Length for children under age 2 years should be obtained in the supine position using a length board. After 2 years of age, standing height should be obtained using a wall-mounted stadiometer.

Weight, height, and BMI for children age 2–19 years should be plotted on the 2000 CDC growth charts.[14] For infants and children under 2 years of age, the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics recommend that weight, length, weight-for-length, and head circumference be plotted on WHO growth charts.[14] The WHO charts were developed using longitudinal data from infants in six countries who were breastfed during the first year of life. In contrast with the cross-sectional data collected from predominantly formula-fed infants for the 2000 CDC growth charts, breastfed infants show a greater growth velocity than formula-fed infants during the first months of life, with subsequent slower rates of weight gain throughout infancy.[14] The use of WHO charts among US children will likely reduce the prevalence of growth failure diagnoses in early childhood,[13,14] but may increase the prevalence of growth failure diagnoses in the first six months of life.[104] Infants born preterm should have their chronologic age corrected for gestational age until they reach 24 months of age for weight, 40 months for length, and 18 months for head circumference.[105] Children with a genetic syndrome, including Down and Turner syndromes, should be plotted on syndrome-specific growth charts.

Shifting between growth percentiles is common in the first 2 years of

life, especially during the first six months. Mei[106] and colleagues studied over 10,000 children from birth to age 5 years participating in the California Child Health and Development Study from 1959 to 1967. The study included children from diverse socioeconomic backgrounds but did not include Latinos. 29% of infants between birth and 6 months of age, 6%–15% of children between 6 and 24 months of age, and 1%–5% of children between 24 and 60 months of age crossed 2 major weight-for-age percentiles. Shifts in weight-for-height occurred more commonly in each age group. The authors speculate that the frequent shifts in growth percentiles might be explained by regression to the mean, genetic predisposition, measurement error, or random variation.[106]

The common occurrence of shifting growth curves underscores the importance of a longitudinal approach to growth monitoring combined with a comprehensive history and physical examination to discern normal variations in growth from growth failure. Evaluation should include a careful family history with attention to the growth and pubertal history of parents and siblings. Genetic height potential should be calculated and compared to child centiles (Table 47-5).[107] Figure 47-2 illustrates characteristic linear growth curves for children with intrinsic short stature, constitutional or delayed growth, and growth failure related to undernutrition or disease (attenuated growth).[108]

TABLE 47-5 Calculating Genetic Height Potential

Boys	(Father's Height + Mother Height + 13 cm) divided by 2 Or (Father's Height + Mother's Height) divided by 2 + 6.5
Girls	(Father's Height + Mother's Height – 13 cm) divided by 2 Or (Father's Height + Mother's Height) divided by 2 – 6.5

Plot the end result on the appropriate growth chart at the age of 20 y to determine the predicted adult height percentile.

Source: Tanner et al.[107]

Normal variations in growth include genetic or familial short stature, and constitutional growth delay. Children with genetic or familial growth delay may cross percentiles downward but will maintain a normal growth velocity once they reach their genetically determined height percentile, and bone age will match chronological age.[109,110] Children with constitutional growth delay have a normal birth weight and length, and cross percentiles downward in the first 2–3 years of life, followed by a normal growth velocity.[110] In children with constitutional growth delay, bone age will be

delayed compared to the chronological age. They will also have puberty later than their peers, resulting in a normal adult height.[109]

Children with growth failure related to undernutrition will classically show a decline in weight percentile, followed by a decline in linear growth percentile. Weight-for-length reflects current nutritional status and helps to identify growth failure related to undernutrition or disease.[10] Children with malnutrition will usually display a drop in weight-for-length percentile over time,[10] although chronic malnutrition can result in stunting and a relatively normal weight-for-length, especially if a child has received nutritional intervention. Children with endocrine disorders will often have a normal or elevated weight-for-length in addition to short stature.[110] Head circumference is typically the last anthropometric measure to be affected by malnutrition.

APPROACH TO EVALUATION OF THE PATIENT WITH GROWTH FAILURE

A detailed history and physical examination are the most important components in the assessment of a child with growth failure, guide both diagnostic tests and treatment approach.[111,112] The process of history-taking can be the first step in establishing a therapeutic alliance between the medical team and the family or caregiver(s) that will allow successful treatment of medical, behavioral and psychosocial factors contributing to a child's growth failure.

Medical History

Past medical history, medication use, and immunization history should be detailed. Acute illness can increase metabolic demands through fever and stress responses, as well as decrease caloric intake through anorexia. A history of recurrent or unusual infections should increase suspicion for underlying immunodeficiency. Special attention should be paid to early life history. This includes maternal prenatal history, including use of drugs, possibility of prenatal infections, maternal nutrition, and health during pregnancy; birth history, including labor and delivery; birth size; and neonatal events. Difficulty with feeding and other diagnoses at nursery discharge have been associated with later growth problems.[63] Developmental history should be reviewed in detail.

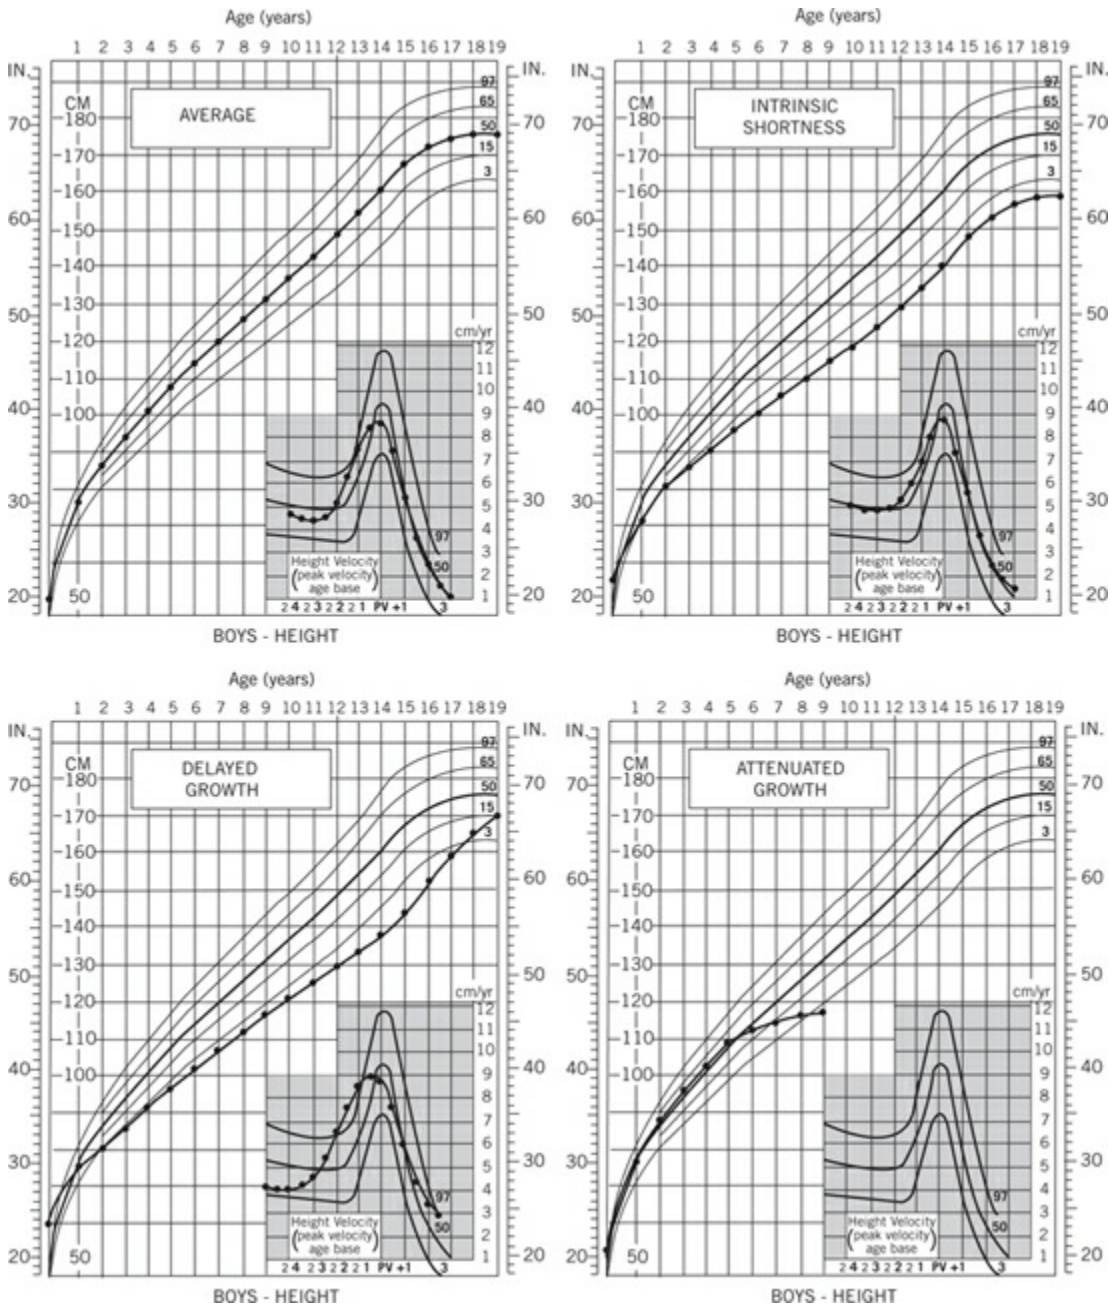

Figure 47-2 Linear growth curves (and height velocity curves, *insets*) of four different patterns of growth: average, intrinsic shortness or familial short stature; delayed or constitutional growth, and attenuated growth. The attenuated growth pattern is classically associated with malnutrition. Adapted from Schaff-Blass et al.[108]; reprinted with permission from the *Journal of Pediatrics*.

A thorough review of systems, with particular attention to the gastrointestinal, respiratory, allergy, and neurologic symptoms, will help

screen for underlying medical conditions. Gastrointestinal review should assess for dysphagia, vomiting, abdominal pain, and stool pattern (frequency, consistency). Symptoms suggestive of oromotor difficulties include choking, gagging, pouching, adverse reactions to foods, or aversion to specific textures or flavors. Symptoms and signs of aspiration are shown in Table 47-6.[43] An underlying inborn error of metabolism should be suspected when symptoms include: recurrent episodic vomiting, lethargy or dehydration; jaundice or liver dysfunction; developmental delay, seizures, hypotonia or other neurologic findings; impaired vision or hearing; organomegaly; and dysmorphic features.[113] The nutritional history should include a comprehensive, culturally appropriate assessment of food intake and feeding history from birth. The timing of introduction of solid foods should be obtained. The current types, quantities, and schedules of all foods and liquids should be obtained, and any adverse reactions to foods should be elicited. A 24-hour recall or 3-day food diary may be used, but a multiday food diary can be challenging in some families. Parents or caregivers should note the amount eaten rather than the amount served. For infants, breastfeeding latch, frequency, night feedings, and any difficulties with breastfeeding should be discussed. Formula type and preparation should be detailed; improper formula mixing can lead to insufficient caloric intake.[114] A feeding behavior history identifies feeding difficulties and may provide insight into their origins. Routines surrounding mealtime should be probed, and information including who provides meals, the setting in which meals are provided, the use of modeling at mealtime, the presence of distractions during mealtimes, and the duration of meals may provide information on specific behaviors that can be modified.[115] To identify potential goals for behavioral therapy, data regarding feeding patterns should be obtained, including: how children are introduced to new foods; whether infants or children are allowed to self-feed; whether cups or utensils are used; whether coercive or restrictive feeding patterns exist; and details regarding rewards or punishment used for feeding behaviors.

TABLE 47-6 Symptoms and Signs of Aspiration

Blinking, eye watering
Throat clearing, grimacing, head tilting
Difficulty handling oral secretions
Poor oral motor co-ordination
Limited endurance/increasing fatigue during feeding
Delayed swallow reflex

Multiple swallows to clear single bolus Wet voice quality during or after feeding Increased congestion during feeds Noisy/wet upper airway sounds associated with feeding Coughing or choking with feeds Change in breathing rhythm or apnea Recurrent wheeze Recurrent respiratory infection
Source: Reprinted with permission from Andrew et al.[43]

Family history should include parental and sibling weight and heights, and the age of onset of puberty. The child's genetic height potential (Table 47-5) should be calculated. A family history of illness that can cause growth failure, such as celiac disease, inflammatory bowel disease, thyroid dysfunction, cystic fibrosis, congenital heart disease, or other major organ disease, in addition to psychiatric or eating disorders, may be helpful in guiding the medical evaluation.

The social history should include the level of parental education, parent employment and job strain, household financial status and living conditions, and the mental health status of caregivers. The caregiver's perception of the child's nutritional status should be obtained as this can influence feeding patterns.[86] Family knowledge of appropriate child nutrition, as well as facilitators and barriers to purchasing, storing, and preparing food should be explored.

Physical Examination

Each child's height, weight and head circumference should be plotted on the appropriate WHO, CDC, or syndrome-specific growth chart (as described in the "Screening and Diagnosis" section above) and interpreted in the context of their family's growth history and pattern. The longitudinal trajectory of a child's growth curve can provide insight into an underlying medical condition or provide support of a diagnosis of health. In addition to the child's growth trajectory, the severity of malnutrition should also be evaluated. Gomez criteria, Waterlow criteria, or anthropometric z-scores can be used to categorize the severity of malnutrition. Severe, chronic malnutrition may indicate risk for refeeding syndrome and necessitate hospitalization for monitoring upon replenishment of calories.

Measurement of triceps skinfold values and mid-arm circumference is used to quantify adipose stores,[116] and can help the clinician distinguish whether slower than expected growth is related to genetic potential,

constitutional delays, or underlying illness. Depleted fat stores accompanying decreased growth velocity supports undernutrition as an underlying etiology. Use of skinfold measurements can be limited by the need for adequate training of personnel, special equipment and availability of reference standards. Published age- and sex-specific reference standards for pediatric skinfold and mid-arm circumference are available.[117]

A comprehensive physical examination to assess for underlying medical conditions, developmental status, and nutritional status should be performed. Table 47-7 summarizes possible findings on physical examination in children with growth failure that are suggestive of underlying medical problems or nutritional deficiencies.[118] Caregiver-child interaction is a critical component of the physical exam, including physical proximity, verbalization toward each other, affect, and eye contact. Attention to signs of abuse or neglect should be sought by examining general hygiene, oral health, and skin. Table 47-8[7,119] lists findings that should alert health care providers to explore neglect.[57]

TABLE 47-7 Physical Examination Findings that Suggest Underlying Cause of Growth Failure or Micronutrient Deficiency

	Clinical Sign(s)	Suggested Underlying Cause
Vital signs	--	Adrenal or thyroid insufficiency
	Hypertension	Renal disease
	Tachypnea/tachycardia	Increased metabolic demands
Skin	Pallor	Anemia
	Poor hygiene	Neglect
	Ecchymoses	Abuse
	Petechiae, ecchymoses	Vitamin C or K deficiency
	Candidiasis	Immunodeficiency
	Eczema	Allergic disease
	Erythema nodosum	Ulcerative colitis, vasculitis
	Diffuse pigmentation	Protein energy
	Xerosis, follicular keratosis	Vitamin A or essential fatty acid deficiency
	Perifolliculosis with blood or pigment	Vitamin C deficiency
	Pellagrous dermatosis	Niacin or tryptophan deficiency

	Scrotal or vulval dermatosis	Riboflavin
Hair	Hair loss	Stress
	Thin, sparse, easily pluckable	Protein energy malnutrition, zinc
Ears	Chronic otitis media	Immunodeficiency, structural orofacial defect
Eyes	Cataracts	Congenital infections, galactosemia
	Papilledema	Increased intracranial pressure
	Uveitis	Vasculitis
	Pale conjunctivae	Iron, folate, or vitamin B_{12} deficiency
	Bitot's spots, conjunctival or corneal xerosis, or keratomalacia	Vitamin A deficiency
	Angular palpebritis	Riboflavin or niacin deficiency
Nose	Nasolabial seborrhea	Riboflavin, niacin, or pyridoxine deficiency
Oropharynx	Aphthous stomatitis	Crohn's disease
	Tonsillar hypertrophy	
Lips	Angular stomatitis or cheilosis	Riboflavin, niacin, iron, or pyridoxine deficiency
Teeth and gums	Delayed tooth eruption	Delayed bone age
	Milk bottle caries	Neglect
	Swollen, bleeding gums	Vitamin C deficiency
Tongue	Ageusia, dysgeusia	Zinc
	Glossitis	Niacin, folate, riboflavin, iron, vitamin B_{12}, pyridoxine, tryptophan deficiency
	Atrophic filiform papillae	Folate, niacin, riboflavin, iron, or vitamin B_{12}
Neck	Thyroid enlargement	Thyroid disease, iodine deficiency
	Parotid enlargement	Protein energy
Chest	Wheeze	Cystic fibrosis, asthma
	Murmur	Congenital malformations
	Cardiomegaly, tachycardia	Thiamine deficiency
Abdomen	Distention, hyperactive bowel sounds	Malabsorption
	Hepatosplenomegaly	Liver disease, glycogen storage disease, malignancy; protein energy malnutrition

Genitourinary	Anomalies	Associated endocrinopathies
	Diaper rashes	Diarrhea, neglect
Rectum	Fistulae	Crohn's disease
	Empty ampulla	Hirschsprung's disease
Extremities	Edema	Hypoalbuminemia, protein energy malnutrition, thiamine deficiency
	Clubbing	Chronic lung disease
Nervous system	Abnormal deep tendon reflexes	Cerebral palsy; vitamin B_{12} or E deficiency
	Developmental delay	Altered caloric intake or requirements
	Cranial nerve palsy	Dysphagia
	Psychomotor changes, confusion irritability	Protein energy malnutrition
	Sensory loss, motor weakness, calf tenderness	Thiamine deficiency
	Loss of vibratory sense, decreased deep tendon reflexes	Vitamin B_{12} or E deficiency
Musculoskeletal system	Loss of muscle mass	Chronic or protein energy malnutrition
	Decreased subcutaneous fat	Protein energy malnutrition
	Craniotabes, frontal bossing, rachitic rosary, epiphyseal enlargement	Vitamin D deficiency
	Epiphyseal enlargement, subperiosteal hemorrhage	Vitamin C deficiency
Nails	Koilonychia	Iron

TABLE 47-8 Recognition of Growth Failure Secondary to Abuse or Neglect

Risk factors for neglect

- Parental depression, stress, marital strife, divorce
- Parental history of abuse as a child
- Mental retardation and psychological abnormalities in the parent(s)
- Young and single mothers without social supports
- Domestic violence
- Alcohol or other substance abuse
- Previous child abuse in the family
- Social isolation and/or poverty
- Parents with inadequate adaptive and social skills

Parents who are overly focused on career and/or activities away from home Failure to adhere to medical regimens Lack of knowledge of normal growth and development Infant with low birth or prolonged hospitalization
Signs of possible abuse or neglect that may arise during treatment
Intentional withholding of food Strong beliefs in health and/or nutrition regimens that jeopardize a child's well-being Family resistant to recommended interventions despite multidisciplinary team approach
Source: Adapted from Block, et al.[57]

Observation of a feeding in the clinic can provide insight into the medical and behavioral factors that may be contributing to the feeding difficulties.[120] Home visits by trained professionals, such as a behavioral psychologist or feeding specialist, or videotaped meals may provide additional insight in the infant or child's typical mealtime environment. In addition to identifying oromotor problems that impact chewing or swallowing, family dynamics and environmental interactions can be observed (Table 47-9).[120] Specific behavioral recommendations can be tailored to the individual patient and caregivers based on behaviors observed during the recorded feeding.

Ancillary Studies

Laboratory and radiographic studies should be guided by the history and physical examination, to look for specific underlying disease or complications related to undernutrition. More than three decades ago, Sills reported that laboratory testing in children with poor growth is unlikely to be diagnostically helpful in the absence of suggestive symptoms and/or signs.[112] Among 185 children under age 3 years hospitalized for FTT (weight < 3rd percentile or crossed 2 major percentiles downward), only 36 of the 2607 laboratory tests were of diagnostic utility.[112] All 36 of these test results were suspected based on information obtained during the medical history and physical examination. In a similar 1982 study of 122 hospitalized infants between 1 and 25 months of age, 0.8% of the approximately 40 tests per infant yielded diagnostic information toward the etiology of FTT.[111] These studies suggest that a careful history and physical examination acts as a less invasive and more efficient screen for medical disease in children with growth failure than a "shotgun" approach to laboratory screening. Still, some caution is needed in applying the results of these studies, both published more than 30 years ago, to modern

medical investigation of growth failure. For example, celiac disease, which can present with growth failure as the sole manifestation,[121,122] now has highly accurate screening blood tests and appears to be increasing in prevalence over time. Our understanding of the spectrum of early childhood clinical presentation of eosinophilic esophagitis, a recently identified condition, is evolving.[123,124] New studies to determine the utility of diagnostic testing in growth failure, particularly in the absence of other concerning symptoms or signs, would be helpful to guide clinicians in minimizing the number of tests while confidently identifying treatable causes of growth failure.

TABLE 47-9 Key Details of Feeding Observation

	Key Feeding Behaviors
Parent	Anxiety Inattention Force feeding Bothered by food messes Does not allow child participation in feeding Props bottles Ignores child's feeding signals
Child	Cries Spits up Gags Vomits or ruminates Holds food in mouth Back arching Plays with food or toys at mealtime Takes more than 30 min to eat Refuses to stay seated

Source: Reproduced with permission from Corrales et al.[181]

A complete blood count and iron studies can be considered to check for iron deficiency anemia. Iron deficiency anemia has been commonly reported in growth failure,[97] and children at particular risk include unsupplemented preterm infants, infants consuming excessive cow's milk or juice, or infants who have been exclusively breastfed past 6 months of age without iron supplementation. Urinalysis and urine culture are reasonable to check for urinary tract infection. Isolated renal tubular acidosis is a rare cause of growth failure; screening with venous blood gases rather than serum biochemistry may be more accurate in detecting acidosis.[125] Tissue transglutaminase IgA and total serum IgA should be

performed to screen for celiac disease. Stool studies are indicated for diarrhea, to assess for malabsorption and/or infection. A modified barium swallow may be needed if aspiration or oromotor dyscoordination is suspected. Head ultrasound or MRI should be considered for an increasing head circumference or other symptoms and signs suggestive of an intracranial mass.[126] In immigrant children and international adoptees, there is a higher risk for complications related to undernutrition and recommendations for health care and screening in this group should be followed.[93] For children from areas where HIV is endemic, HIV screening is indicated.

Lead concentration and erythrocyte protoporyphrin levels can be considered, especially in children at high risk for lead exposure. In a small case-control study, high lead levels were more common among children with FTT[127]; however, the current prevalence of high lead levels among US children with growth failure is likely to be lower, given that the prevalence of elevated blood lead levels >= 10 mcg/dL declined from 8.6% in 1988–1991 to 1.4% in 1999–2004.[128] Prevalence of high lead levels among US children has declined even in historically high-risk groups.[128]

For patients presenting with short stature, endocrine conditions such as hypothyroidism or growth hormone deficiency and genetic syndromes such as Russell-Silver, Turner, or Down syndrome must be considered as potential etiologies. Laboratory evaluation for short stature should include TSH, free T4, IGF-1, and IGFBP-3 levels in addition to the laboratory evaluation described above.[109] For female patients, karyotype can be ordered to check for Turner's Syndrome. A bone age radiograph can help determine a child's growth potential.[129] Referral to a pediatric endocrinologist should be made for suspected endocrine abnormalities. Children born small for gestational age with a length-for-age z-score < −2.5 at 2 years should be referred to endocrinology for consideration of growth hormone therapy[130]; in such children, growth hormone treatment started at age 2–4 years and continued over a three-year period has been associated with height gains ranging from 1.2 to 2.0 standard deviations.[25]

MANAGEMENT OF GROWTH FAILURE

The management of growth failure requires long-term treatment that may involve nutritional counseling, behavior modification, feeding therapy, and social work assistance based on the contributing factors identified during

the history and physical examination. Management of mild growth failure typically occurs in an outpatient setting. Successful treatment of any underlying medical conditions will often be associated with improved nutritional status and growth, but attention to nutrition is still needed to reduce complications and mortality.[131]

The medical, nutritional, feeding, and psychosocial aspects in growth failure are often best managed using a multidisciplinary team approach.[132–134] The team may include a physician, dietitian, feeding specialist (usually a speech and language pathologist or occupational therapist), social worker, and behavioral psychologist. In addition to a team approach in the clinic setting, home visits by a home health nurse or community health worker may have some benefit on growth outcomes in childhood.[135,136]

Hospitalization may be warranted in cases of severe malnutrition to allow for monitoring of hemodynamics, electrolytes (refeeding syndrome), and feeding tolerance, or when there are concerns regarding caregiver competence, child neglect or abuse.[137] In cases of severe feeding refusal, admission may be required for initiation of nasogastric tube feeds. Children recovering from severe malnutrition may gain weight safely on caloric intakes as high as 170 kcal/kg/d and protein intakes of 4–5 g/kg/d.[138] However, in the United States, this extreme level of macronutrient needs is unusual.

Caloric needs for catch-up growth can be estimated using prediction equations that take estimated stress and activity into account. In a study of children with growth failure that compared predictive equations to measured resting energy expenditure (REE), the Schofield equation was least likely to underestimate REE.[139] Additional calories for catch-up growth can be calculated in the following manner[82]:

1. Determine the child's Dietary Reference Intake (DRI) for age
2. Determine the child's ideal weight-for-height or ideal weight-for-age (50th percentile on appropriate sex-specific growth chart)
3. Multiply DRI for age by ideal weight
4. Divide by child's actual weight

Protein needs can be calculated in a similar manner. The caloric requirements used as a basis for nutritional counseling should be intermittently adjusted based on weight and height gain over time. Nutritional and feeding interventions should be tailored to the appropriate developmental stage.

For a child with growth failure, the goal for catch-up growth is to cross percentiles upward to attain a normal weight-for-height and ensure that they reach their genetic potential for linear growth. One published criterion for adequate catch-up growth is to exceed, by 2–3 fold,[9] the average age-specific growth rates published by Guo et al.[116] These widely cited growth rates were calculated using data from two small, regional US cohorts that were not nationally representative and were comprised of predominantly formula-fed infants; calculated age-specific mean growth rates based on WHO growth data would differ slightly.

The ideal target amount of catch-up growth, and the speed at which it should be achieved, continues to be debated, with several factors to consider.[140,141] In resource-poor environments, among children born low birth weight or with a history of growth failure, catch-up growth is associated with reduced morbidity and mortality from infections,[141] and improved cognitive function. In a study pooling data from longitudinal cohorts in five developing nations, higher weight gain between 0 and 2 years was associated with more schooling and decreased risk of grade failure.[142] SGA infants who show catch-up growth display improved cognitive outcomes.[143] However, in both developing and developed nations, excessive catch-up growth has also been associated with greater adiposity, insulin resistance, and cardiovascular disease in childhood and adulthood[140]; rapid infant weight gain during the first few months of life may confer the greatest cardiometabolic risk in later life.[140] Further research is required to determine the optimal timing, magnitude and tempo of catch-up growth that best balances associated benefits and potential adverse effects.[140,144]

There is a paucity of high quality studies (longitudinal data and/or randomized controlled trials) examining which nutritional and feeding interventions in toddlers and children are most effective in treating growth failure related to undernutrition in the outpatient setting, especially among children without cognitive impairment. Further, there is no clear consensus as to how best to describe feeding behavior interventions and outcomes that may affect growth. A 2011 systematic review of 31 studies from high-income countries reported that a parental restrictive feeding style was associated with higher BMI, and parental pressure during feeding was associated with lower BMI and weight gain in childhood[145]; the authors pointed out that 25 of the 31 reviewed studies were cross-sectional, raising the possibility of reverse-causality, and 16 different feeding measures were used across studies. Childhood growth is a commonly studied outcome in

intervention trials in developing nations, but the myriad of factors affecting growth failure specific to these settings may limit the generalizability of these studies to developed nations.[146] Consequently, recommendations discussed below are based on limited controlled studies, published guidelines by experts in the field, and our own clinical experience.

Nutritional and Feeding Interventions for Infants

Growth failure in breastfeeding infants may be related to maternal factors, such as milk supply, or infant factors, such as poor latch or suck. These factors should be thoroughly explored as a potential cause for inadequate energy intake, to allow infants continued access to the nutritional, immunologic, and psychosocial benefits of breastfeeding. Maternal milk supply may be increased by stimulating milk supply with breast pumping or increased feeding frequency, advising maternal rest and hydration, targeting stress reduction, and modifying home and work environments to allow for breastfeeding.[4] Consultation with a lactation specialist may assist with infant latch and suck, and may also be helpful for infants who are irritable during feeds as a response to strong milk let down. Infants with neurodevelopmental or anatomical conditions that preclude safe and sufficient breastfeeding may need to drink expressed human milk from a bottle or feeding tube; thickened feeds may be indicated for infants with aspiration.

Infants who are irritable with feeds may have cow's milk protein intolerance, gastroesophageal reflux, or difficulty with swallowing. Treatment of these conditions is discussed in detail elsewhere in this text. Optimal postdischarge nutrition for preterm infants is also discussed elsewhere in this text.

When a breastfeeding infant with inadequate caloric intake is unable to gain weight despite interventions to increase milk supply and improve breastfeeding technique, supplementation with formula should be considered.[147] Growth failure should be verified on WHO growth charts and referral to a lactation consultant should be considered before starting formula supplementation. If formula supplementation is started, powdered formula can be added to expressed breast milk, or bottle feeds with formula can be introduced after breastfeeds based on information obtained during evaluation.

In formula-fed infants, communication with caregivers is a key to understanding the underlying reasons for poor growth so that specific

behaviors that may be contributing to undernutrition can be targeted for intervention. Infrequent, short duration, or small volume of feeds may be identified as underlying reasons for insufficient caloric intake. If an increase in the volume of daily feeds is not tolerated or is ineffective, the caloric density and protein content of formula can be increased.[148] Powdered formula can be increased from the standard 20 kcal/oz up to a maximum of 26 kcal/oz through concentration. If further increases in caloric density are needed, commercially available modulars may be added to a typical maximum of 30 kcal/oz. The daily caloric needs and fluid requirements of infants should be kept in mind and hydration status monitored.

In older infants, age-appropriate solids may be targeted for increasing caloric intake. Adding powdered formula or cooking oil can increase the caloric density of cereals or purees. A dietitian should be consulted when increasing the caloric density of breastmilk, formula, or solids.

Nutritional and Feeding Interventions for Toddlers and Children

The main goal of nutrition therapy is to increase oral intake of calories and nutrients. Healthy, nutrient-rich and calorically dense foods should be offered. The density of calories can be increased in healthy foods through the addition of oils, avocado, sour cream, heavy cream, butter, peanut butter, and cheese. High calorie foods with low-nutritional value such as candies, desserts, and fried foods should be avoided as they can lead to a preference for unhealthful foods associated with adverse cardiometabolic health risks in later life. Fruit juice or sugar-sweetened beverages should be avoided.

Age-appropriate nutritional supplement drinks typically provide 30 kcal/oz, and if used, should be offered after solid foods rather than in lieu of them. Feeding recommendations should be given within the context of cultural preferences, particularly in the case of immigrant families and adoptees. A multivitamin containing iron and zinc may be helpful to ensure that common micronutrient deficiencies are avoided.

Cyproheptadine, an antihistamine appetite stimulant, can be a useful adjunct to stimulate appetite in toddlers and children with inadequate intake. In a systematic review of 12 placebo-controlled randomized controlled trials in children and adults, we found that cyproheptadine is efficacious in achieving weight gain.[149] The dose used in the five pediatric studies of children age 3 months to 14 years ranged from 2 to 12 mg/d

divided two to three times daily, and the medication was generally well-tolerated. Many physicians will alternate a few weeks' use of cyproheptadine with a one to two weeks drug holiday, due to possible tachyphylaxis, but none of the reviewed studies used a cycling regimen.

If feeding difficulties are present, information regarding normal developmental progression of feeding and guidelines regarding behavioral feeding strategies should be provided. It is common for caregivers of a child with growth failure to experience stress around mealtimes or to feel the need to control the amount and type of foods that their child eats.[150] Concrete guidelines regarding the recommended meal schedule, setting, and specific foods to be offered are helpful in both reducing caregiver stress and in treating or preventing problematic feeding behaviors.

As part of normal development, older infants and young children want to touch their food and self-feed as they develop independence and motor ability. Physicians can help parents understand their own concerns about mess, control, and loss associated with their baby growing up.[4] Allowing self-feeding with spoons or fingers, even in children with growth failure, is important to promote healthy eating and development.[151] However, a young child may not be able to feed themselves sufficient calories for growth without assistance. Parents should not force a child to drink or eat predetermined amounts of liquids or foods because forceful feeding can worsen feeding disorders or lead to post-traumatic stress disorder.[79] Feeding and behavioral therapists may be able to assist parents in understanding hunger and satiety cues and avoid restrictive or forceful feeding habits that can perpetuate growth failure or lead to oral aversion.[79]

The concept of the division of feeding responsibilities as discussed by Satter may be helpful for parents to develop strategies to reduce stress around mealtime[151]: parents are responsible for providing safe and appropriate foods in a supportive manner while children are responsible for deciding how much and what they will eat. Parents should be advised that they are shaping the child's food preferences in early life.[152] Most children will refuse new tastes and textures the first time they are exposed, but as foods become more familiar they are more likely to be accepted.[153] If families can set realistic goals about the variety and amount of foods that children eat, mealtime battles, and aversive behaviors may be avoided.

The meal setting and schedule should be structured to promote healthy eating behaviors and improve caloric intake.[79] One case control study found that disorganized mealtime structure and family dysfunction was more prevalent in 4-year-old children whose growth fell below the 10th

percentile for height and weight, compared with controls with normal growth.[154] Offering meals or snacks every three hours and with the child sitting in a high chair or booster seat can promote child recognition of hunger and satiety cues and ability to self-regulate feeding. Limiting meal and snack duration to 30 minutes and avoiding grazing between meals and snacks may facilitate greater intake. Providing foods first and then liquids afterwards may prevent children from feeling full from liquids before eating their meals. Parental modeling of eating nutritious foods and the mechanisms of chewing may encourage child intake of nutritious foods. Elimination of distractions such as TV or toys can also be helpful. Making mealtime social with caregivers providing positive comments about food and eating may help encourage children to take in sufficient amounts of food.

For infants or toddlers with severe eating disorders, such as severe feeding refusal or selectivity among cognitively impaired children, long-term treatment in intensive day programs or inpatient treatment may be needed.[76] The behavioral modification interventions used in programs for feeding difficulties vary, but usually combine more than one technique, including escape prevention, extinction, contingent or positive reinforcement, texture fading, planned ignoring, among other techniques.[76] More research is needed regarding which techniques and what combinations of techniques might be effective in nondevelopmentally delayed children.

CONSEQUENCES AND PROGNOSIS

Limited information exists regarding the long-term growth outcomes of full-term infants with growth failure in developed countries. A few small case-control studies suggest that children with severe growth failure in early life experience improvement in their somatic growth, but continue to have lower weights and heights than age-matched controls later in childhood.[155–158] Boddy et al.[158] reported that among 42 children from a 1986 UK birth cohort with a WFA < 3rd percentile for at least three months duration identified at 12 months of age, mean weight-for-age z-score improved from −2.09 at 12 months of age to −0.97 at 6 years of age. Among controls from the same birth cohort matched for age, birth weight, gender, social position, ethnic group, and area of residence, mean weight for age z-score was 0.094 at 12 months and 0.68 at 6 years. Mean height for age z-score was −1.26 in cases and −1.76 in controls at 12 months, and −0.91 in cases and 0.27 in controls at 6 years. A 2005 systematic review

identified eight controlled studies and five uncontrolled studies assessing the growth and cognitive outcomes of children with FTT[159]; the authors concluded that children with FTT were shorter and weighed less than control children at follow-up ranging from three to nine years later, but that few children were below the 3rd percentile at follow-up. Subsequent to publication of the systematic review, Drewett et al.[156] compared children from a 1987 birth cohort within the slowest 5th percentile of weight gain, to 91 controls, and found that the adjusted mean difference at age 12 was 4.3 cm for height, and 7.2 kg for weight. Interpretation of these studies is challenging because of the potential for selection bias in case-control studies, and the inability to clearly delineate the role of nutrition, genetics, or other factors in the growth of study subjects. For example, only 2 of the 5 case-control studies in the systematic review controlled for parental height.[159]

Among term infants born small for gestational age, the majority will show improvement in anthropometric parameters within the first 2 years of life,[160,161] but mean weight and height in childhood and adulthood remain lower than for infants of normal birth weight.[162] In the National Perinatal Collaborative Cohort, compared with children with a birth weight > 2500 g, children born at ≥ 37 weeks with a birth weight ≤ 2500 g had lower mean weight-for-age z-score (−0.60 SD) and height-for-age z-score (−0.50 SD) at age 7 years.[27] These differences correspond to an average height deficit of 2 cm and an average weight deficit of 1.6 kg at 7 years of age. In the same study, 22% of siblings born SGA had age 7 weight < 10th percentile, compared with 12% of siblings not born SGA, suggesting that genetic rather than environmental factors account for the persistent effects of SGA on growth.[27] In a French cohort, term infants born with a birth weight or length below the 3rd percentile were a mean of 3.9–4.5 cm shorter at age 20 years, than infants born with a normal birth weight (25th–75th percentile).[163]

Several retrospective and prospective case-control studies show that the majority of preterm infants with growth failure do attain normal weights and heights in later life, but compared to term, normal birth weight peers, infants born with extremely or very low birth weight exhibit lower mean weight-for-age and/or height-for-age in the first few years of life,[20,164–166] in adolescence,[167] and in adulthood.[166,168] One small study of 195 US VLBW preterm infants (birth weight < 1500 g) suggested sex-specific differences in adult body composition.[168] Compared with normal birth weight, term, sex-matched controls, VLBW males were a mean of

3.1 cm shorter ($P < .01$) and weighed 10.5 kg less at age 20 years, whereas females were a mean of 1.2 cm shorter and weighed 2 kg less and these differences were not statistically significant. Nevertheless, the majority of VLBW infants achieved adult weight and stature within normal limits. Among male VLBW infants, 11% had adult height-for-age z-score < −2 and 7% had adult weight-for-age z-score < −2. Among females, 2% had adult height-for-age z-score < −2 and 5% had adult weight-for-age < −2; the mean differences in these outcomes were not statistically significant, although there was probably insufficient power to detect a subtle effect. Moderate (32–35 weeks)[169] and late preterm birth (34–36 weeks)[19] has also been associated with lower weight and height in childhood.

Separating the individual effects of preterm birth and small for gestational age on growth outcomes was difficult in early cohort studies which tended to use weight-based inclusion criteria, but recent studies have attempted to examine the individual effects. Preterm infants with short maternal height and those born SGA appear to be at the highest risk of short stature.[166] In one Dutch study of 1338 children born at < 32 weeks gestation and/or birth weight < 1500 g, the height of 10-year-old children born SGA was −0.29 SD lower than for children born AGA.[170] In a French study of 1,597 infants born at < 33 weeks gestation, 24% of infants born SGA had short stature at age 5 year (height z-score for age and sex < −2).[171] International adoptees from orphanages often have significant catch-up growth in weight and height after adoption.[93,172] A meta-analysis of 33 studies showed substantial gains in height and weight after adoptive placement.[172] Among 148, 7 to 59-month-old children adopted from Eastern Europe, 62% showed a gain of >+0.5 units in height z-score at six months after adoption.[173] Only 7% of children had a height z-score < −2 at six months after adoption, and two of these children had growth hormone deficiency.[173] Physicians should advise adoptive parents to allow three to six months for evidence of improved growth velocity before intervening, unless a medical condition is suspected. This period of monitoring may help avoid the negative consequences of rapid weight gain, including obesity, cardiovascular, and adverse metabolic outcomes.[93]

Early life feeding difficulties have been associated with long-term feeding habits. Children with picky eating or feeding refusal may have feeding problems later in childhood.[79,174] Less commonly, an undiagnosed anxiety or autistic spectrum disorder may be uncovered later in childhood.[4,79] Children with severe eating disorders may require long-term intensive multimodal therapy that includes behavior modification, family

counseling, education, and feeding therapy. Some children with underlying medical or neurologic disorders may need ongoing enteral tube feeding supplementation.

In developing nations, severe childhood malnutrition has been clearly associated with adverse cognitive, health, and social outcomes.[175] In the United States and other developed nations, the effect of slow weight gain on cognitive outcomes is less clear.[159,176,177] Two systematic reviews published several years ago examining the cognitive sequelae of failure-to-thrive came to differing conclusions. Definitions for FTT were variable across studies. A 2004 systematic review of 31 studies (11 uncontrolled) of "nonorganic failure-to-thrive" concluded that "FTT in infancy is associated with adverse intellectual outcomes sufficiently large to be of importance at a population level."[177] The overall weighted standard mean difference for 10 controlled studies was estimated at −0.28, corresponding to a mean IQ difference of 4.2 points. The magnitude of the associations with cognitive outcomes was larger among the three studies where cases were identified from hospitals or specialist clinics vs. population screening. The effect size decreased substantially between infancy and later in childhood; in a few longitudinal studies with repeat measures, the mean summary effect estimates (D-statistics) were −0.51 to −0.61 at 1 year, and −0.22 to −0.24 in the same children at 6 years of age. A 2005 systematic review included 13 studies of failure-to-thrive for any reason and had growth or psychomotor development outcomes at 3 years or older, of which eight had a comparison group and two were randomized controlled trials.[159] A meta-analysis of the four studies that reported IQ scores at follow-up yielded a pooled standardized mean difference of -0.22 (95% CI −0.41 to −0.03), roughly equivalent to −3 IQ points.[159] Although the effect size was fairly consistent with the prior meta-analysis, the authors felt that this effect size was "of questionable clinical significance." They also concluded that it was unclear to what extent observed differences reflected confounding by variables such as birth weight, maternal height, and socioeconomic status, which were not consistently controlled for across studies; in most of the studies, the control groups displayed mean cognitive testing scores that were lower than population norms, bringing into question whether the results are generalizable to populations with higher cognitive function.

Nutritional, social, environmental, and genetic factors have the potential to modify the associations between growth failure in early childhood and later cognitive and other health outcomes. The association between chronic iron deficiency anemia and long-term irreversible

developmental delays best illustrates the link between micronutrient deficiency and developmental outcomes.[178,179] In addition to iron, it is possible that other micronutrient deficiencies could modify the associations between early growth failure and health outcomes in later life. In one small intervention study of weekly structured play home visits delivered over two years, malnourished children who received the intervention had better cognitive test scores at age 6, than malnourished controls who had not received the intervention.[180] These findings emphasize the importance of comprehensively addressing the psychosocial, medical, nutritional, and environmental factors to optimize anthropometric, cognitive, and other health outcomes for each child who presents with growth failure.

SUMMARY

Growth failure usually arises from the interaction of medical, social, and environmental factors that result in a final common pathway of undernutrition. Commonly associated risk factors include short parental height, preterm and/or SGA size at birth, maternal depression during infancy, and behavioral feeding disorders. Each potential contributing domain is best explored by a multidisciplinary team to tailor the assessment and management. The history and physical examination should guide the judicious use of laboratory investigations. Treatment in the outpatient setting focuses on optimizing the feeding environment, schedule and caloric density of offered foods and beverages. Key research priorities include development of consensus regarding the optimal criteria for the diagnosis of growth failure and feeding disorders; additional randomized studies of feeding interventions; and long-term prospective studies of health outcomes among children with growth failure in developed nations.

Developmental Disabilities

48

Kelly A. Dougherty, PhD
Babette S. Zemel, PhD

Children with moderate-to-severe disabilities have a markedly increased risk for malnutrition. Neurologic abnormalities—resulting in altered physical activity (voluntary and involuntary), fine motor patterns, and oral-motor patterns—will often significantly affect food intake and nutrient requirements. Chronic undernutrition, characterized by growth failure and reductions in fat stores and lean body mass, is the most common form of malnutrition, but overweight and obesity also occur. Despite these clinical observations, only limited research-based information on the nutrient needs and nutritional status of children with severe disabilities is available. Consequently, recommended nutrient intakes and growth pattern expectations for this group of patients are poorly defined and must be approached on an individual basis.

Nutritional status assessment is essential for identifying the undernourished or overnourished child, estimating the optimum energy intake to promote growth and well-being, and monitoring treatment. In children with moderate to severe disabilities, nutritional assessment is complicated by the interaction of the primary disease process (e.g., muscle atrophy, contractures, central nervous system pathology, or movement disorders) and both chronic and acute malnutrition. Cerebral palsy (CP), a common disability with significant risk for malnutrition, will be used as a model to describe the nutritional needs and nutritional status of children with severe disabilities.

Close to 90% of children with CP require at least some assistance with feeding based upon oral-motor dysfunction[1,2] and acquisition of eating skills is associated with gross motor functional ability.[3] Established in 1996, the North American Growth in Cerebral Palsy Project (NAGCPP)

was a large, population-based study that recruited subjects from six centers in the United States and Canada to investigate growth, nutrition, functional outcomes and overall quality of life in children with CP. Results showed that in children ages 2 to 18 years with moderate to severe CP, 30%–40% had severe feeding difficulties.[4] Parent-reported feeding dysfunction was strongly associated with poor health and nutritional status as well as severity of motor impairment. Those orally fed (nontube fed) showed a dose response relationship between severity of feeding dysfunction and growth and body fat (energy) stores, suggesting a pattern of inadequate energy intake. The authors recommended using a structured feeding dysfunction questionnaire to screen for nutritional risk in children with CP. Similar findings from a large population-based cohort study conducted in England showed that feeding difficulties reported by parents in the first four weeks of life in children with CP were associated with more severe neurodevelopmental impairments and an increased likelihood of being underweight by school age, suggesting that early, persistent, and severe feeding difficulties are a marker for future growth failure.[5] The association of feeding difficulties and nutritional status in CP has been demonstrated in every population studied.[1,4–8] Feeding difficulties and nutritional status also are associated with increased health care utilization and decreased societal participation by the child and parents.[9,10]

The timing of introduction of feeding assistance for those with oral-motor dysfunction may be important. In a recent registry-based study in Norway,[11] encompassing approximately 80% of children born with CP born between January 1, 1996 and December 31, 2003 (n = 661), 21% of the sample was completely dependent on feeding assistance, including tube feeding (in 14%). Speech function was highly associated with the need for feeding assistance. Duration of gastrostomy tube feeding was positively associated with weight and BMI z-scores, but was not associated with improved height status. However, age at placement of the gastrostomy tube was inversely associated with both height and weight status, independent of gross motor impairment, underscoring the importance of early intervention to promote growth and nutritional status.

Several important nutritional issues were recognized in these studies. Assistance with feeding, prolonged feeding times, and choking significantly affect food intake.[1,2] In addition, gastrointestinal problems, such as reflux, vomiting, and constipation, and some medications, such as those used to treat seizures, contribute to alterations in both nutritional intake and requirements.[2,12] Food intake low in energy density is of

particular concern because of the marked linear growth failure,[6,7,9] delayed skeletal[13–16] and sexual maturation,[17] poor weight gain, and reduced energy reserves seen in patients with CP.[18] Despite lower total energy expenditure in children with CP,[12] the energetic cost of physical activity in ambulatory children is greater than in typical children.[19] Increased muscle tone is also associated with greater resting energy expenditure.[20] Although protein intake usually meets recommended levels, lower concentrations of markers of protein metabolism in children with CP, particularly those fed enterally, suggest that needs are not met.[21] Abnormal body composition, with reductions in muscle and fat stores, and a high prevalence of undernutrition (failure to thrive, marasmus) and less frequently overnutrition (overweight, obesity) have also been noted.[18,22,23] Some specific nutrients are at risk, particularly vitamins C, A, and D; iron; and calcium, but micronutrient needs of children with neurologic impairment requires further research.[24] Low bone density,[22,25–27] associated with degree of immobilization, hypovitaminosis D, feeding difficulties, and lower triceps skinfold measurements in children with CP, also has been reported. Risk of fracture in children with moderate to severe CP is high, and is associated with low bone density,[28] greater body fat, feeding by gastrostomy tube, and prior history of fracture.[29]

For children with CP, the drug–nutrient interactions of anticonvulsant medications and vitamin D were demonstrated by several investigators in the 1970s. Vitamin D deficiency and insufficiency continues to be a concern in the nutritional care of these children.[30–32] Some classes of anticonvulsants, through the action of the hepatic microsomal enzymes, cause increased vitamin D catabolism. In a survey of 125 noninstitutionalized children with heterogeneous types of CP in the United States, nearly 20% had low serum 25-hydroxyvitamin D levels. However, low vitamin D status was not associated with severity of CP, growth failure, or use of anticonvulsants.[32] Another study of institutionalized children in South Africa found that anticonvulsant therapy was associated with long-bone fracture, and that 3 months of vitamin D and calcium supplementation resulted in marked improvement in serum calcium and phosphorus, and reduced alkaline phosphatase and fracture rate.[33] Another vitamin D and calcium supplementation study demonstrated improved bone mineral density (BMD) in children with CP.[32] Weight-bearing physical activity focused on normal movement patterns[34] vibration platforms,[35] or loaded sit to stand exercises combined with virtual training

cycling[36] also has a beneficial effect on bone. Thus, in addition to anticonvulsants, low dietary intake of vitamin D and calcium, limited physical activity and low sunlight exposure also contribute to rickets, osteopenia, and pathologic fractures in children with CP.[37–40]

Nutritional assessment of children with severe disabilities has several components, including evaluation of dietary intake, growth status, body composition, energy expenditure, bone density and laboratory data in the context of the nutritional risk factors related to the medical history, physical examination, diagnosis, and current therapy. The need for interdisciplinary evaluation and treatment of nutrition and feeding abnormalities for children and adults with CP has been addressed by numerous investigators and position papers.[10,41–44] Inadequate energy intake is a primary concern. Children with CP have abnormal growth and body composition. Therefore, conventional methods for estimating energy requirements based upon prediction equations that use body weight or surface area, may be inappropriate for nonambulatory children with CP.[45,46] The Dietary Reference Intake (DRI) recommendations for energy from the US Food and Nutrition Board[47] base the estimated energy requirement (EER) on age group, gender, physical activity level, height, weight and weight status (healthy weight vs. overweight), so these recommendations may prove to be more appropriate for children less severely affected with CP. The importance of determining energy requirements and meeting those requirements in children with CP is underscored by several nutrition intervention trials in which energy supplementation by gastrostomy or nasogastric feeding tube resulted in improvements in various components of nutritional status.[48–52]

Another approach to determining energy needs in children with severe CP has been to determine the extent of growth failure and poor nutritional status, and their relationship to nutritional and disease-related factors and energy expenditure. A multicenter study of growth and health outcomes in North America documented the association of growth failure with indicators of overall health and social participation across the spectrum of CP, showing that children with the best growth status had lower health care utilization and fewer days of social participation missed.[9] In a large single center study (*N* = 142), children ages 2–18 years with spastic quadriplegic CP (SQCP) participated in a survey of growth and nutritional status.[6,7] Linear growth, assessed by upper-arm and lower-leg lengths, was significantly reduced (z-scores, –1.57 to –2.38) relative to typically developing children.[53] Weight and triceps skinfold thickness were, on

average, about 65% of age- and sex-specific medians for children in the United States; subscapular skinfold thickness was 81% of the median. Poor nutritional status was evident in children as young as 2–4 years of age. Linear growth retardation in upper-arm and lower-leg length was significantly associated with poor nutritional status (arm muscle area, percent body fat), after adjusting for disease severity (diagnosis, cognitive ability, oral-motor function, ambulatory status, gastrostomy feeding, and dyskinetic component) and nondisease variables (age, gender, race, pubertal status, and midparental height). This analysis demonstrated that the large effect of poor nutritional status on linear growth was independent of, and additive to, the effects of the severity of the CP and nondisease factors.

Energy expenditure and dietary intake were measured in a subsample of these children with SQCP. Resting energy expenditure (REE), expressed as the percentage of the predicted value from World Health Organization (WHO)[54] prediction equations, was considerably lower than in typically developing children (91% predicted in CP vs. 105% in controls). REE was lowest (88% predicted) among the majority group of poorly nourished children with CP.[12] Total energy expenditure, measured by the doubly labeled water method, was also lower than in control children, in keeping with reduced physical activity in children with severe SQCP. The physical activity factor, or ratio of total to REE, was 1.23 for children with CP as opposed to 1.57 for controls. This is similar to the patterns of resting and total energy expenditure observed in adults[55] with CP. Thus, in children with SQCP, energy requirements are lower than in normal children. However, determination of energy intake proved to be far more difficult. The ratio of total energy intake, measured by a three-day weighed food intake diary, to total energy expenditure indicated a large—about 50%—overestimation of food intake by the caregivers of these children with poor oral-motor function.

Other studies have confirmed the lower total energy expenditure and physical activity factors for children with CP,[19,56,57] except for children with good ambulation. These findings illustrate the complexity of assessing energy requirements in disabled children. Although total energy requirements are lower in children with severe CP, dietary intake is likely to be grossly overestimated in the clinical setting. The prevalence of chronic undernutrition and growth failure in many children with SQCP indicates that energy needs are not being met. The next sections outline an approach to determining energy requirements in children with CP or other severe disabilities. The first step is the assessment of growth and

nutritional status to identify those children whose energy needs are not being met and the degree of past or current undernutrition. Methods for estimating energy requirements based on nutritional status and related factors are reviewed.

NUTRITION STATUS ASSESSMENT

Inadequate energy intake appears to be a major cause of nutrition-related growth failure in children with CP. Thus, two clinical management needs arise: (1) methods to assess nutritional and growth status to identify patients who are undernourished or overnourished and (2) methods to determine the energy requirement of the individual patient. The elements of complete nutritional assessment are based on the standard pediatric medical evaluation and are presented in more detail in Chapters 2 and 3.

The medical history includes assessment of acute and chronic medical problems and medications. In addition, a nutritional history, including review of a "typical" day's food intake; dietary history; use of energy, vitamin, mineral, herbal, or other nutritional supplements; and unusual food practices by the child or family are obtained. The past growth patterns, including pubertal history and growth charts, are reviewed. The history includes a review of systems, with emphasis on dental and oral-motor function and on the gastrointestinal tract (emesis, gastroesophageal reflux, diarrhea, constipation).

The physical examination includes current pubertal status[58]; weight; height, length, or alternative linear growth measures; head circumference; mid-arm circumference; and skinfold measurements. Interpretation of anthropometric measures requires comparison with children of similar age and sex in order to determine growth and nutritional "status." In addition to the reference ranges established for typically developing children, a number of publications offer values based on children with CP. Krick et al.[59] provided the first CP-specific growth charts for height, weight, and weight-for-height for children with quadriplegic CP based on 1,630 observations on 360 children at a single center. Malnourished children were not excluded from the sample, so these curves do not represent the optimal growth pattern of adequately nourished, healthy children with quadriplegic CP. The NAGCPP multicenter study also produced growth curves for weight, knee height, upper arm length, mid upper arm muscle area, triceps skinfold and subscapular skinfold for children with moderate to severe CP,[9] but the curves were not published as a reference; they were created to demonstrate the effect of nutritional status and degree of

neurologic impairment (i.e., gross motor function classification) on growth status. Height, weight and BMI growth charts stratified by motor and feeding skills in children with CP have since been published based on close to 142,000 observations on 24,920 children with CP in the California Department of Developmental Services.[60] Using a similar data source, Brooks et al.[61] published growth charts for weight stratified by age and gross motor function classification system constructed from over 100,000 weight measures in children with CP. These authors showed increased morbidity and mortality of children with low weight-for-age depending on gross motor function classification. These charts were designed to mimic the CDC charts and there were no exclusion criteria for poor nutritional status. Studies are needed to establish their utility in clinical care and validate their effectiveness in recognizing unhealthy weights to support treatment changes. Details of the recommended methods, equipment, and reference standards for the anthropometric measurements are in the following section. (For an overview of some of the physical findings associated with nutritional deficiencies, see Appendix, Table I-8.)

The laboratory evaluation is focused by recognizing the risk factors identified from the history and physical examination for each individual patient. The primary nutritional problem is usually inadequate energy intake, and laboratory assessment of this pattern of malnutrition is of limited use. Both serum albumin and prealbumin can be indicators of the adequacy of calorie and protein intake, with albumin reflecting the past month (half-life, approximately 18–20 days) and prealbumin reflecting the past week (half-life, approximately 2–3 days) of nutrient intake. However, these are often in the normal range with the chronic under-nutrition associated with CP. Iron-deficiency anemia is seen in groups of patients who have limited energy intake or who have monotonous food intake with few iron-rich foods. Iron status evaluation includes a complete blood count (hemoglobin, hematocrit, and red cell indices) as a screen, followed by other iron studies (serum iron, total iron-binding capacity, transferrin, ferritin) as indicated. Response to iron therapy is monitored by changes in the components of the complete blood count and a reticulocyte count.

Laboratory tests are selected depending on the patient's history and physical examination and could include serum values for vitamin D, calcium, phosphorus, and alkaline phosphatase, and radiologic examination of long bones to diagnose rickets. Clinically significant osteopenia often occurs without rachitic changes and can be diagnosed by determining bone mineral content or bone density [dual-energy x-ray absorptiometry (DXA)]. Bone density of the distal femur has been

proposed as a measure for children with CP and contractures who are difficult to position for standard measurement sites.[62–65] Skeletal age determination[66,67] is useful for diagnosing nutritional dwarfism in children with a delay of 2 or more years in bone age and for determining the potential for catch-up growth. Blood values for selected vitamins and minerals are available when indicated.

ANTHROPOMETRY

Anthropometric evaluation of growth and nutritional status is an essential component of nutritional care. It is a rapid, inexpensive, noninvasive means of determining both short- and long-term nutritional status. A well-trained anthropometrist is required in order to ensure accurate, reproducible measurements. Numerous anthropometric measures are used in the assessment of nutritional status. Each measure offers different information, and no single measure is sufficient for characterization of nutritional status. Proper equipment should be used, and it should be calibrated regularly to ensure accurate measurements. When accurate measurements are obtained and compared with appropriate reference standards, the clinician obtains a current classification of nutritional status and an opportunity to see changes in status over time. Guidelines for anthropometric measurement techniques are available[68] and are summarized below with consideration of the child with developmental disabilities.

Measurement of Growth

Weight, stature or length, and head circumference should be measured at routine office visits and every hospital admission. Current status and increments in growth between visits are very informative, especially for tracking progress in the individual patient. For children with severe disabilities, segmental measures of the arm or leg offer alternative measures of linear growth (upper-arm length, lower-arm length, lower-leg length, and knee height). These are described below for assessment when a length or stature measurement is not possible.

Weight

Because growth retardation is common in children with severe disabilities, it is of extra importance that both weight and linear growth are measured at the same time. Excess weight can be attributable to excess fat, excess

water caused by edema, or organomegaly, so other anthropometric measures, such as arm circumference and skinfold thicknesses, are important complements in interpreting a weight measurement.

Equipment, Measurement Technique, and Reference Standards

Weight should be measured on a digital electronic or beam balance scale. The scale should be checked weekly with known calibration weights. The measurement should be taken to the nearest 0.1 kg in older children and to the nearest 0.01 kg in infants.

The scale should be reset to zero prior to placing a child on it. Children should be weighed wearing little or no outer clothing and without shoes. Infants should be measured without diapers. Wheelchair-accessible scales are available for older children who cannot stand unattended on a scale. The measured weight of the wheelchair alone is deducted from the weight of the child (with little or no clothing) in the wheelchair.

For reference standards for weight, see WHO growth charts[69] for infants and children ages 0–2 years of age and Centers for Disease Control and Prevention (CDC) 2000 growth charts[70] for children age 2 years and older. Additionally, CP-specific growth charts are available[60,61] (see also http://www.lifeexpectancy.org/articles/GrowthCharts/All.pdf).

Length or Stature

Linear growth is a measure of a child's nutritional history and genetic potential; it helps to distinguish between short- and long-term nutritional problems. Length or stature measurements are appropriate for children who can be properly positioned, as described below. For children less than 2 years of age or children older than 2 who are not able to stand erect unsupported, a supine length measurement is taken. Standing height, or stature, is measured at age 2 and older. In older children with developmental disabilities, a length measurement is often required past 2 years of age. When comparing a supine length measurement to a growth chart for stature, the length should be decreased by 0.7 cm[71] to adjust for the known difference between length and stature measurements.

Equipment, Measurement Technique, and Reference Standards

To measure supine length, an infantometer or an inflexible length board with a fixed headboard and a movable footboard should be used. Length is measured to the nearest 0.1 cm. Infantometers and stadiometers with digital counters should be calibrated daily with a calibration bar of fixed

length, or following manufacturer's guidelines.

Measurement of supine length requires two people to position and hold the child. The head should be placed at the top of the board, with the Frankfurt plane perpendicular to the floor.[72] The Frankfurt plane extends from the lower margin of the orbit to the upper margin of the auditory meatus (Figure 48-1). An assistant is needed to hold the head firmly in this position. The knees should be flattened to fully extend the legs. The feet should be together and flexed to a 90° angle by the footboard with the infant fully stretched.

To measure stature, the child should stand with the heels, buttocks, and back of the head against the stadiometer. The arms should be down and relaxed and the heels together. The position of the head should be adjusted so that the Frankfurt plane is parallel to the floor. Stature should be measured using a stadiometer with a head paddle that glides smoothly but is firmly perpendicular to the back of the stadiometer. Alternatively, a tape measure permanently fixed to a wall or doorframe can be used provided that a head paddle is available that will fit at a 90° angle to the wall. Both length and stature measurements should be accurate to 0.1 cm.

Length and stature measures are inappropriate for children with spinal curvature, contractures, or other conditions that prevent proper positioning for the measurement. Segmental measures of arm or leg length are alternatives under these conditions (see below).

For both length and stature, measurements should be taken in triplicate, with the measurements in agreement within 0.5 cm, and the mean recorded. Whenever possible, the statures of both biological parents should be obtained and midparental stature computed (the average stature of the mother and father). Adjustment of stature or length measurements using midparental stature charts is a technique that recognizes and corrects for differences in the genetic potential for linear growth.[73]

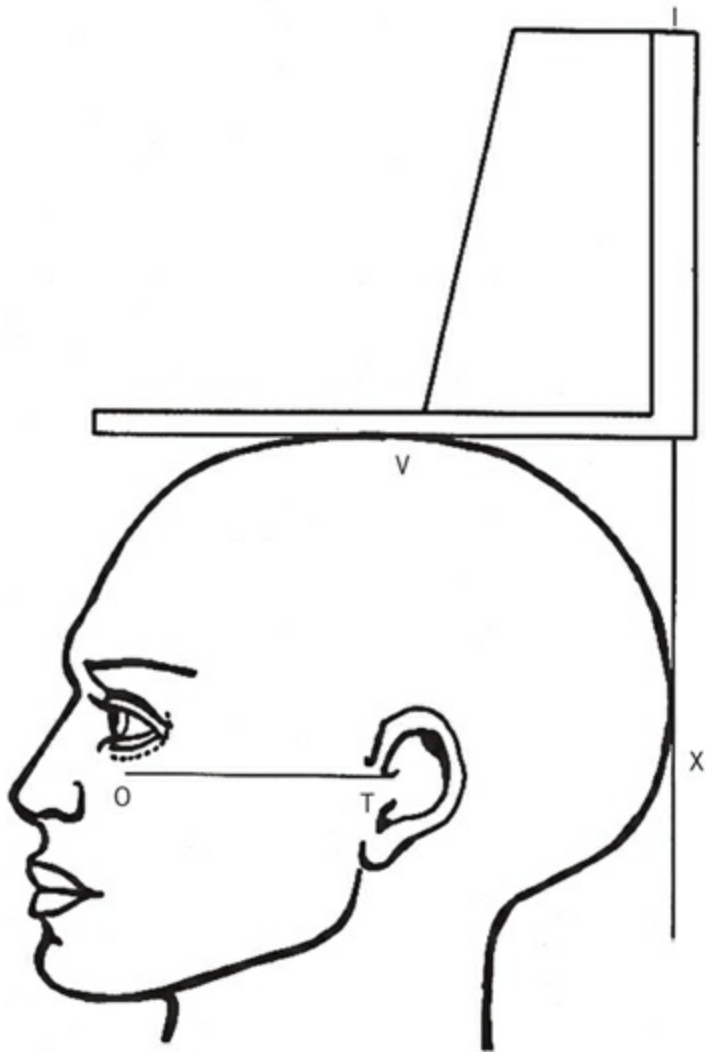

Figure 48-1 The Frankfurt plane extends from the auditory meatus to the lower border of the orbit. This plane should be parallel to the paddle or headboard when measuring stature or length. Reproduced from Ross et al.[72]

For reference standards for length and stature, see WHO growth charts[69] for infants and children ages 0–2 years of age and CDC 2000 growth charts[70] for children age 2 years and older. Additionally, CP-specific growth charts are available.[59,60] (see also (http://www.lifeexpectancy.org/articles/GrowthCharts/All.pdf).

Weight-for-Height Indices

Weight-for-length and weight-for-height indices are important in the

assessment of nutritional status to ensure energy reserves adequate for maintaining growth and over-all health. For infants and children ages 0–2 years of age, weight-for-length and weight-for-height charts are available[69] to assess nutritional status. Additionally, CP-specific weight-for-height[59] are available. For children more than 2 years of age, the body mass index (BMI) can be used. BMI is calculated as weight in kilograms divided by height in meters squared (wt/ht^2). Reference standards for BMI for typically developing children from birth to 20 years are available.[69,70] Use of these charts is essential for interpretation of BMI in the pediatric range. Additionally, CP-specific charts for BMI are also available.[60] (see also http://www.lifeexpectancy.org/articles/GrowthCharts/All.pdf).

Head Circumference

Brain growth is most rapid in the first 3 years of life. Head circumference is a good indicator of brain growth and therefore should be included in the assessment of growth and nutritional status. Because of the high risk of growth failure in children with developmental disabilities, it is important to measure head circumference until age 3, or longer in some children, to determine whether growth of the brain and head is also compromised. However, head circumference is of limited use in nutritional status assessment of patients with central nervous system damage and micro- or megalocephaly of non-nutritional etiology.

Equipment, Measurement Technique, and Reference Standards

A flexible metal or non-stretch plastic-coated measuring tape scaled to 0.1 cm should be used. The tape is placed over the supraorbital ridge and around the occiput so that a maximum circumference is obtained. Care should be taken that the tape is evenly placed on all sides and is flat against the skull. Three measurements should be obtained and the mean recorded.

For reference standards for head circumference, WHO growth charts[74] for infants and children ages 0–2 years of age, and CDC 2000 growth charts for children ages 2–3 years of age[70] are recommended. For older children see Roche and colleagues.[75]

Arm and Leg Length Measures

Segmental measures of the arm and leg are alternative measures of linear growth when length or stature measurements are not possible. This commonly occurs in children with developmental disabilities. Both upper-

arm and lower-leg length should be measured because they provide measures of upper- and lower-body long-bone growth. Frequently, lower-leg length is more compromised than upper-arm length in children who are nonambulatory. Measurement of knee height[76] and ulnar length[77] are additional alternative measure of linear growth and can be used in prediction equations to estimate height.

Equipment, Measurement Technique, and Reference Standards

For young infants, sliding calipers (0–200 mm) are used. For older infants and children, an anthropometer (50–570 mm) or segmometer (Rosscraft Innovations, Inc.) is used. All measurements should be taken in triplicate to the nearest 0.1 cm and the average used. For infants and young children up to 24 months of age, upper-arm length is measured as shoulder-to-elbow length. With the arm flexed at a 90° angle, the upper arm is measured from the superior lateral surface of the acromion to the inferior surface of the elbow. In children 2–18 years of age, upper-arm length is measured from the superior lateral surface of the acromion to the radiale (head of the radius) with the arm relaxed, as shown in Figure 48-2.

Ulna length[77] is measured with the patient seated and left arm resting on a table with the elbow bent at 90°–110°. The hand should be positioned with the palm faced down and fingers extended and together. The measurement is taken from the proximal end of the ulna (olecranon) to the tip of the styloid process.

Figure 48-2 Upper arm length measurement technique.

For infants and young children, lower-leg length is measured as a knee-to-heel length. With the infant lying supine—with the leg flexed to 90° at the hip, the knee, and the ankle—the lower-leg length is measured from the heel to the superior surface of the knee. For older children, a comparable measure is knee height, taken in a seated position with similar 90° flexion at the hip, knee, and ankle. For children 2–18 years of age, the tibia length, also known as the lower-leg length measure is taken from the distal margin of the medial malleolus to the proximal border of the medial tibial condyle while the patient is sitting in a relaxed position, as shown in Figure 48-3. The right side should be measured unless there is unilateral involvement affecting the right side. The least affected side should be measured and thus noted on the growth chart so that repeat measures are always taken on the same limb.

Reference percentiles for upper-arm length and lower-leg length for

typically developing infants and toddlers are given in Figures 48-4 and 48-5, and for older children (3–18 y) in Figures 48-6 through 48-9. These are derived from work by Spender and colleagues[53] and Snyder and colleagues.[78] Recently, tibia length growth curves for ambulatory children with CP (gross motor function classification system levels I, II, and III) have been published based on 750 participants and nearly 1200 observations.[79] Reference percentiles for ulna length in typically developing children ages 5–19 years, and corresponding height prediction equations based on ulna length are presented by Gauld et al.[77] and for knee height by Chumlea et al.[80] Choice of which segment to measure may depend on characteristics of the individual patient, such as ambulation status, contractures and deformities, and difficulty in positioning. Selection of reference percentiles based on children with CP can be used to assess the status of an individual child relative to other children with CP. However, because of the pervasive nutritional issues in children with CP, these reference percentiles are unlikely to represent “optimal” growth.

Nutritional Status

Anthropometric indicators of nutritional status consist of measurements of lean and fat tissues at sites known to be sensitive indicators of nutrition and health. Upper-arm anthropometry, the measurement of arm circumference and skinfold thickness, is particularly useful because excellent reference data are available for clinical interpretation. An additional measure of subcutaneous fat on the trunk, the subscapular skinfold thickness measure, is helpful for further assessing total body fat stores, especially when fat distribution is abnormal.

Mid-Upper-Arm Circumference

Mid-upper-arm circumference is a composite measure of muscle, fat, and

bone in the arm. It is sensitive to current nutritional status and can be used in combination with the triceps skinfold thickness measure to estimate upper-arm muscle area and upper-arm fat area.

Equipment, Measurement Technique, and Reference Standards

A nonstretch flexible tape measure is used. All measurements should be taken in triplicate to the nearest 0.1 cm. The midpoint of the upper arm is located by measuring the length of the upper arm (from the tip of the acromion to the olecranon with the arm flexed at 90° and the palm facing upward) and marking the midpoint with a washable ink pen. The mid-arm circumference is taken with the arm down and in a fully relaxed position. Gently shaking the arm usually ensures that it is relaxed. The tape is placed over the midpoint perpendicular to the long axis of the arm. Care should be taken so that there is no pinching or gaping of the tape as it encircles the arm. This process improves the accuracy and reproducibility of the measure.

For reference standards for mid-upper arm circumference, see Frisancho[81] and the WHO Multicentre Growth Study.[74]

Skinfold Thickness

Skinfold thickness measures assess subcutaneous fat at specified sites. The triceps and subscapular skinfold measures are indicators of total body fat stores and are sensitive to changes in nutrient intake and nutritional status. Depletion of fat stores at the triceps site is common in children with CP and in other chronically undernourished groups, whereas fatness at the subscapular site is not affected as severely.[6,7,82] Reference data for the sum of these two skinfold measures are available[83] and are used in the research setting as a characterization of total body fat.

Equipment, Measurement Technique, and Reference Standards

Holtain skinfold calipers are preferred because they are scaled to 0.2 mm. Lange calipers can be used, but with some loss of accuracy as they are scaled to the nearest 0.5 mm. Calipers that are not spring-loaded and therefore do not provide a constant tension are not recommended.

The triceps skinfold thickness is measured over the triceps muscle, along the back of the arm. The measurement is taken at the same level at which the mid-upper-arm circumference is measured. The patient should be upright with the arm down and fully relaxed for the measurement. The fold of fat and skin is lifted away from the underlying muscle and held

throughout the measurement. The calipers are placed next to the fingers lifting up the skinfold; the skinfold is held in position while the thickness is measured with calipers, and the reading should be taken three to four seconds after releasing the caliper's handles.

For the subscapular skinfold, the patient should be upright with the arm and shoulder down and fully relaxed. The skinfold is lifted 1 cm below the tip of the scapula at a 45°angle following the natural contour of the body. The fold is held in place, and the calipers are placed next to the fingers holding the fold. The reading should be taken three to four seconds after releasing the caliper's handles.

A number of different sources for skinfold thickness reference standards based on typically developing children are available.[74,83–85]

Body Composition

Body composition assessment, the measurement of fat and lean body mass stores, is an essential component of nutritional assessment of the disabled child. Whereas linear growth reflects the longer-term nutritional history and genetic potential and is often compromised in children with disabilities, fat and lean body mass stores reflect short-term nutritional adequacy. Body composition can be estimated using the prediction equations of Slaughter and colleagues[86] based on typically developing children ages 8–18 years. These equations use the triceps and subscapular skinfold thickness measures shown in Table 48-1. Specific equations are given based on race, gender, and pubertal status groups. Adjustment factors (for sex, race, puberty status, level of obesity, and gross motor function) to the Slaughter equations for children with CP (ages 8–18) have also been published,[87] but have not been independently validated.

Body composition values estimated from the Slaughter et al.[86] anthropometric prediction equations have been compared with measures determined from total body water[18] in children with severe SQCP. Fat mass measured by these two methods is significantly correlated (r = .69), indicating that the anthropometric prediction equations is a reasonable estimate to be used as a clinical, noninvasive method to estimate total body fat in children with CP. Other methods, such as bioelectrical impedance analysis (BIA)[57] and DXA,[87] are possible. However, motion artifact and inability to properly position the patient could increase the measurement error and give inconsistent results in children with moderate to severe disabilities. In addition, most BIA devices require a height measurement, although a recently published prediction equation by Reiken et al.[57] uses

tibia length. For children whose height can be estimated only from long-bone measures, the measurement error is greatly increased so that BIA methods may become less effective measures of body composition. In a small sample (n = 8), Liu et al.[88] compared estimates of body composition by BIA and anthropometry with DXA in eight children with CP and severe motor impairment. Results showed correlation coefficients for DXA versus other methods for fat-free mass determination were excellent (r = .9) but only moderate for fat mass and percent body fat (range 0.4–0.8). The best predictor of percent body fat was skinfolds and of fat mass was bioelectrical impedance.

Bone Density Assessment

Children with moderate to severe CP are at increased risk of osteopenia and fracture,[27–29] so assessment of bone density is often warranted. Bone density is measured by DXA, a rapid, noninvasive technique that involves very low levels of ionizing radiation. The current recommendation of the International Society for Clinical Densitometry for assessment of bone density in children is to measure the BMD of the lumbar spine and whole body, and compare the results to age and gender-specific reference data to determine the z-score (standard deviation). A z-score less than or equal to –2 is considered "low" BMD.[89]

For many children with developmental disabilities, particularly for those with CP, a whole body and spine measurement may not be feasible due to altered posture, spasticity, voluntary and involuntary movements, and metal spine implants.[64] In addition, the BMD measure is influenced by height and weight, so for children with developmental disabilities and growth failure, a low BMD may be related to poor growth rather than bone strength.[90] An alternative scan technique with accompanying reference data for the distal femur has been developed.[62–65] This has proven to be a more feasible approach for assessing BMD in children with CP and is associated with fracture risk.[28] An example of a distal femur image is given in Figure 48-10. Peripheral quantitative computed tomography (pQCT) has also been used in the research setting to assess bone strength in children with CP.[26] This is not a clinically available assessment technique at this time.

TABLE 48-1 Anthropometric Equations for Prediction of Percent Fat (Ages 8–18

Years)	
White males	
Prepubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 1.7
Pubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 3.4
Postpubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 5.5
Black males	
Prepubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 3.2
Pubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 5.2
Postpubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 6.8
All females	1.33 (triceps + subscapular) – 0.013 (triceps + subscapular)^2 – 2.5
If (triceps + subscapular) greater than 35 mm	
All Males:	0.783 (triceps + subscapular) + 1.6
All Females:	0.546 (triceps + subscapular) + 9.7
CP-specific adjustments	
Overall adjustment	+12.2
Additional adjustment for:	
Males	–5.0
More severe GMFCS	+5.1
Black race	–3.1
Pubescent	+2.0
Postpubescent	–4.6
If (triceps + subscapular) greater than 35 mm	–3.2

Example: for a black postpubescent male at GMFCS level 1 with a triceps + subscapular less than 35 mm, the estimated percent fat = Slaughter percent fat + 12.2–5.0–3.1–4.6.

CP, Cerebral Palsy; GMFCS, Gross Motor Function Classification System.

Adapted from Slaughter et al.[86] and Gurka et al.[87]

ENERGY INTAKE RECOMMENDATIONS

Assessment of energy intake compared to requirement is an essential component of the nutritional care of children with significant disabilities.

Undernutrition and overnutrition are the common nutritional pathologies and are the result of energy imbalance. True energy intake is difficult to determine accurately in children with poor oral-motor function and other gastrointestinal problems. Food loss during feeding and regurgitation contribute to the inaccurate estimation of energy intake, even when weighed food diaries recorded over several days are obtained.[12] Daily energy expenditure and its components can be measured in individuals in a research setting (doubly labeled water, 24-h indirect room calorimetry, REE, thermic effect of food, physical activity). Only REE by indirect calorimetry, a measurement of basal metabolic needs, is available as a clinical evaluation and can be used with estimates of physical activity to predict total energy needs.

There is little information regarding the accuracy of the revised DRI recommendations for energy intake,[47] now designated the EER, for estimating the energy needs of individual patients with developmental disabilities with atypical body size, body composition, and physical activity. The EER is based on gender, age, height, weight and level of physical activity. The formulas for determining the EER are given in Table 48-2. A study of 52 children with CP, ages 2–19 years, generated correction factors (a general correction factor for CP, and additional corrections for high degree of movement and gross motor function classification) to existing prediction equations for total energy expenditure.[57] These equations have not been independently validated.

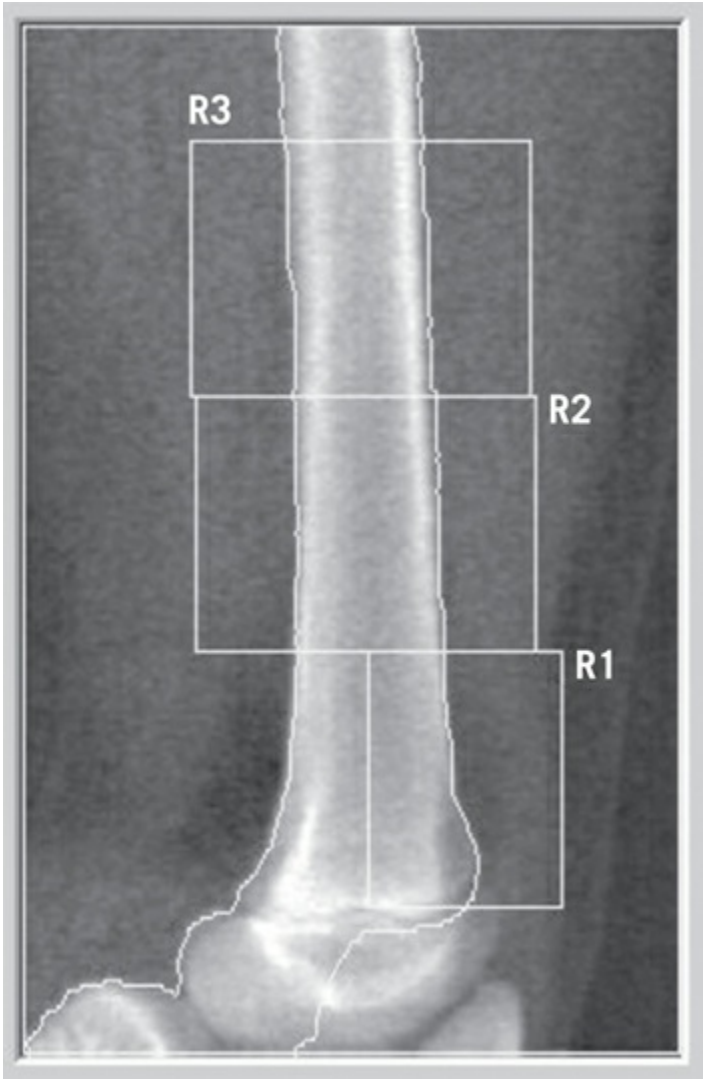

Figure 48-10 DXA scan of a lateral distal femur for assessment of bone mineral density in children. The bone mineral density of regions R1, R2, and R3 are determined separately.

The formulas for energy requirement from WHO[54] allow for individualized prediction of REE based on gender, age, and body weight, as shown in Table 48-3. Whenever possible, REE should be measured by indirect calorimetry in the early morning with the child fully at rest and in a fasting state. Under these conditions, measurements obtained over 30–60 minutes of inactivity can provide an excellent estimate of resting energy needs. Recently, in children with moderate to severe CP, changes in REE over four hours in response to intrathecal baclofen injection was investigated to determine the contribution of high muscle tone to energy

needs in this population.[91] Results showed a significant drop in REE from 101 ± 17% to 84 ± 24% of predicted after injection, suggesting high muscle tone greatly contributes to the energy needs of children with CP. The value for REE, whether from indirect calorimetry or a prediction equation, is adjusted by an activity factor to determine total energy expenditure and daily energy requirements. In normally active typically developing children and in adults with light or moderate activity, the activity factors range between 1.50 and 1.89 times the REE. Overall physical activity is lower in children with CP, but they have a higher energy expenditure during walking compared to typically developing children.[92] Studies are needed to determine how the energetic cost of usual activities affects activity level and total energy expenditure. In children with mild[19] and severe[12] CP, the physical activity factor is much lower ranging from 1.3 to 1.5 times the REE.

TABLE 48-2 Prediction Equations for Estimated Energy Requirements (Kcal per day) for Healthy Children[47]

Infants	Prediction Equations				
0–3 mo	89*weight (kg) – 100 + 175				
3– 6 mo	89*weight (kg) – 100 + 56				
6–12 mo	89*weight (kg) – 100 + 22				
12–24 mo	89*weight (kg) – 100 + 20				
Males	**General Prediction Equation***	**Sedentary PA Coefficient**	**Low Active PA Coefficient**	**Active PA Coefficient**	**Very Active Coeffi**
3–8 y	88.5 – 61.9*age + PAL*((26.7*weight) + 903*(height)) + 20	1	1.13	1.26	1.42
9–18 y	88.5 – 61.9*age + PAL*((26.7*weight) + 903*(height)) + 25	1	1.13	1.26	1.42
> 18 y	662 – 9.53*age + PAL*((15.91*weight)+	1	1.11	1.25	1.48

	539.6*(height))				
Overweight 3–18 y	114 – 50.9*age + PAL*((19.5*weight)+ 1161.4*(height))	1	1.12	1.24	1.45
Females	**General Prediction Equation***	**Sedentary PA Coefficient**	**Low Active PA Coefficient**	**Active PA Coefficient**	**Very Active Coeffi**
3–8 y	135.3 – 30.8*age + PAL*((10*weight) + 934*(height)) + 20	1	1.16	1.31	1.56
9–18 y	135.3 – 30.8*age + PAL*((10*weight) + 934*(height)) + 25	1	1.16	1.31	1.56
> 18 y	354 – 6.91*age + PAL*((9.36*weight) + 726*(height))	1	1.12	1.27	1.45
Overweight 3–18 y	389 – 41.2*age + PAL*((15*weight) + 701.6*(height))	1	1.18	1.35	1.6

*Each prediction equation uses weight (kg) and height (kg), and requires that a physical activity coefficie (PA) be included in the calculation of the EER. The PA categories, based on the physical activity level (calculated as the ratio of total energy expenditure to resting energy expenditure), are as follows:

Sedentary: PAL is estimated to be ≥1.0 and <1.4.

Low Active: PAL is estimated to be ≥1.4 and <1.6.

Active: PAL is estimated to be ≥1.6 and <1.9.

Very Active: PAL is estimated to be ≥1.9 and <2.5.

TABLE 48-3 Equations for Predicting Resting Energy Expenditure (Kcal/d) from Body Weight (w)

Age,y	Male	Female
0–3	60.9 w – 54	61.0 w – 51
3–10	22.7 w + 495	22.5 w + 499
10–18	17.5 w + 651	12.2 w + 746
18–30	15.3 w + 679	14.7 w + 496
30–60	11.6 w + 879	8.7 w + 829
> 60	13.5 w + 487	10.5 w + 596
